This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth and, although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

INHERITED RICKETS

This disease of pigs is indistinguishable from rickets due to nutritional inadequacy. The pigs are healthy at birth. Subsequently there is hypocalcemia, hyperphosphatemia, and increased serum alkaline phosphatase. The defect is a failure of active transport of calcium through the wall of the small intestine.

INHERITED TAILLESSNESS AND TAIL DEFORMITY

Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The condition is thought to be inherited in Holstein cattle and in Landrace and Large White pigs. It is often seen in combination with other deformities of the hindquarters such as atresia ani and urogenital tract abnormalities.

INHERITED DISEASES OF JOINTS

INHERITED ARTHROGRYPOSIS (INHERITED MULTIPLE TENDON CONTRACTURE)

Inherited fixation of limb joints present at birth is recorded in many breeds of cattle especially in the Shorthorn, Charolais, Piedmont, and Swedish Dole. It is thought to be inherited as a single recessive character. There are many environmental causes of the disease, the most common of which is Akabane virus infection of early pregnancy and discussed under that heading.

Simple arthrogryposis

The limbs of affected calves are fixed in flexion or extension and cause dystocia due to abnormal positioning and lack of flexibility. There is no involvement of joint surfaces and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles and those calves which are born alive are unable to stand and usually die or are destroyed within a few days.

Arthrogryposis with dental dysplasia

This defect in cattle appears to be inherited in a dominant manner. The teeth are soft, fleshy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

Arthrogryposis with palatoschisis (SAP)

This is inherited as a simple recessive with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais cattle the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histological changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis with multiple defects

In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wraparound position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in other species than cattle

Inherited arthrogryposis has also been recorded in Merino and Corriedale **sheep**, and in Norwegian Landrace **pigs** in which it is thought to be inherited as a simple recessive. The Corriedale defect is associated with other lesions including brachygnathia inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.[1] Breeding studies using superovulation and embryo transfer were used to increase the numbers of offspring from females which were carrying the gene or genes responsible for the defect which was inherited as an autosomal recessive trait.

An inherited arthrogryposis also occurs in Norwegian Fjord **horses**. The arthrogryposis affects the hindlimbs and there are accompanying defects of polydactyly, palatoschisis, and brachygnathia in some. Most foals are unable to stand and the defect must be considered to be a lethal one.

INHERITED MULTIPLE ANKYLOSIS

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at the 6th to 7th month of pregnancy and this may occasion some respiratory distress. Excessive fetal fluids are present and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion and there is some curvature of the spine. Fetal dystocia always occurs and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with **cleft palate** occurs occasionally in Charolais cattle and is suspected of being inherited. **Ankylosis of the coffin joint**, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in *Bos indicus* cattle and in water buffalo (*Bubalus bubalis*). Shetland ponies also have a predisposition and a monogenic autosomal recessive transmission is suspected.[1,2] There is periodic lameness with the affected limb held in rigid extension; the patella is displaced medially. If the animal shakes the limb the patella may go back into its normal position and the problem is relieved.

INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

This inherited disease is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire which carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifle, hip, knee, elbow, and shoulder joints. The muscles are much atrophied and the joints look very enlarged as a result. It is impossible for the calves to stand but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions, and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, and produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal recessive, it has also been seen in circumstances which preclude inheritance being the cause.

INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Dole horses. There is no clinical evidence of the disease at birth but osteoarthritis of the joint and disruption of the round ligament develop subsequently. For this disease in cattle see 'Degenerative joint disease'.

INHERITED DISEASES OF MUSCLES

GENERALIZED GLYCOGENOSIS (GLYCOGEN STORAGE DISEASE TYPE II)

Generalized glycogenosis is a glycogen storage disease of Corriedale sheep,[1] Shorthorn, and Brahman beef cattle which resembles Pompe's disease in humans.[2,3] Glycogenosis type II in Shorthorn and Brahman cattle is a lysosomal storage disease in which acidic

α-glucosidase is the defective enzyme. In Shorthorn cattle, glycogenosis type II is caused by a single mutation, but the initial DNA/PCR restriction enzyme test of amplicons, was occasionally compromised by inhibition of the restriction enzyme by undefined factors. This was overcome by introduction of wild and mutant allele-specific amplifications and the use of two restriction enzymes, which clarified the anomalies and provided a more accurate testing system.[2]

In Brahman cattle, glycogenosis type II is associated with loss-of-function alleles affecting the α-glucosidase gene that differ from that in Shorthorns. There is a common mutation affecting many Australian Brahmans and a less common one affecting descendants of one imported bull. In addition, a third mutation was associated with significantly reduced α-glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.[3]

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease with lesions present in skeletal and cardiac muscle, and central nervous tissue. During the course of the disease there is progressive muscular damage and acute degeneration of muscle fibers in the terminal stage. Affected Brahman calves die at 8–9 months of age and British breed cattle at over 1 year. Only histopathological lesions are evident and include extensive vacuolation and accumulations of granular material in affected tissues. Amongst the biochemical lesions are greatly diminished α-glucosidase activity in liver and muscle, and a correspondingly high level of glycogen. Animals in affected herds are divisible into normal heterozygotes and homozygotes on the basis of α-1,4-glucosidase activity in lymphocytes or in muscle, especially the semitendinosus muscle.

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available,[2] and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic α-glucosidase gene.[3]

GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)

Glycogen storage disease Type V is one of a number of inherited diseases affecting glycogen metabolism and resulting in abnormal accumulation of glycogen in cells. Glycogen storage disease Type V has been recorded in Charolais cattle in North America.[1] As in Type II glycogenosis, Type V is inherited as an autosomal recessive trait α-glucosidase. There is a deficiency of myophosphorylase, mildly elevated muscle glycogen and elevated serum creatine and aspartate aminotransferase. Severely affected animals may develop rhabdomyolysis which may be accompanied by myoglobinuria.[2]

In Charolais cattle, glycogen storage disease Type V is usually seen in calves at several weeks or months of age and is associated with exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency which may become prolonged. Not all homozygous animals are clinically affected if they are allowed to 'pace their exercise' and some animals have been known to breed despite muscle weakness.

A polymerase chain reaction-restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal.[2] Using a similar test, a Blonde d'Acquitaine cross-bred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and an elevated creatine kinase was considered negative.[3]

FAMILIAL POLYSACCHARIDE STORAGE MYOPATHY (EQUINE RHABDOMYOLYSIS SYNDROME)

This myopathy is associated with exertional rhabdomyolysis and occurs with a high incidence in some Quarter Horse, American Paint, Appaloosa, and Quarter Horse cross-bred families. An autosomal recessive pattern of inheritance is proposed.[4] Recurrent episodes occur at intervals of about 2 weeks. Clinical signs include exercise intolerance with prolonged recumbency in some. Discomfort varies between stiffness and pain suggestive of colic. Myoglobinuria is common during episodes of clinical illness. Serum activity of creatine kinase are elevated. Biopsy of gluteal or semitendinosus muscles reveals polysaccharide inclusion bodies in some muscle fibers and widespread sarcolemmal vacuoles. The defect is basically an error of glycolysis.

INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY

This is an inherited defect in diaphragmatic muscle of Meuse-Rhine-Yssel and Holstein-Friesian cattle[1] appearing in adults and characterized by anorexia, decreased rumination, and eructation leading to recurrent bloat, dyspnea, abdominal respiration, nostril dilation, and death from asphyxia after a course of several weeks. Necropsy lesions comprise degenerative changes in diaphragmatic and thoracic muscles. The immunochemical evaluation of some cytoskeletal proteins of affected muscles found an increase in the amount of desmin and vinmentin immunoreactivities and similar amounts of actin and α-actin compared with controls.[2]

CONGENITAL MYASTHENIA GRAVIS

Congenital myasthenic syndrome has been reported in Brahman cattle in South Africa.[1] Affected calves develop progressive muscular weakness, beginning at birth and up to 3–4 weeks of age. Within 1 week they are unable to stand without assistance. Some calves are able to stand and walk for 30 to 45 minutes before collapsing, but are still able to suck their dams. The calves remain alert and continue sucking but may collapse after 20 to 60 seconds. The weakness becomes progressively worse and affected calves are usually euthanized. Hematology and serum biochemistry are normal, and muscle biopsies do not reveal any abnormalities.

The underlying defect is a homozygous 20-base pair (bp) deletion in the gene, muscular acetylcholine receptor (bov*CHRNE*), coding for the -subunit of the nAChR at the neuromuscular junction.[2] A PCR-based DNA test, using blood or semen has been developed and validated.[3] The test makes it possible to differentiate rapidly and accurately between homozygous wild-type, heterozygous and homozygous affected animals. Preliminary testing of Brahman cattle in South Africa revealed several carrier animals, some of them influential in the breeding population.

BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE

This disease has been reported occurring in Gelbveih cattle in several separate beef herds in the United States.[1] Affected animals are 4 to 20 months of age, and the mortality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histological muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were deficient in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving anti-oxidant metabolism may be the causative factor.

INHERITED UMBILICAL AND SCROTAL HERNIAS, CRYPTORCHIDISM, AND HERMAPHRODITISM

Umbilical hernias in cattle and scrotal hernias and cryptorchidism in pigs have been considered to be inherited defects for many years but the evidence is uncertain.

Umbilical hernias

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age.[1] The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds: the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, factors other than genetic may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein-Friesian cattle can also be conditioned by a dominant character with incomplete penetrance, or be due to environmental factors. In a case control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia.[2] Heifers born to sires with = 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with = 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.[3]

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined.[4,5] An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region >1.5 cm, even if no hernia had developed. Inflammation, abscesses or fistulae were excluded. Data from 53 105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves, the incidence was 2.2%, in females 1.5%. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines but the heritabilty estimates were low varying from $h^2 = 0.04$ (>100 progeny) or $h^2 = 0.05$ (>25 or 50 progeny). However, analysis of the data found no evidence for an autosomal monogenic recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal recessive gene locus, but it seemed much more likely that more than one gene locus is involved or a mixed multifactorial monogenic mode of inheritance may be the underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias and thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull 'Glenhapton Enhancer', have provided evidence that Enhancer is the carrier of major dominant or codominant gene with partial penetrance for umbilical hernia.[3] Five sons of Enhancer produced progeny with >10% frequency of umbilical hernia, whereas the progeny of 3 sons had <3% umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome 8(BTA8). The umbilical hernia-associated paternal allele originated from Enhancer.

Scrotal hernias

Scrotal hernias of pigs have also been shown to be inherited in some breeds, e.g. Duroc and Landrace, but not in others, e.g. Yorkshires.[6]

Cryptorchidism

Evidence suggesting the inheritance of cryptorchidism in swine, sheep, horses, and Hereford cattle and hermaphroditism in swine is also available. Cryptorchidism in horses appears to be inherited with a polygenic pattern of transmission.

MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELLENDER, CULARD)

EPIDEMIOLOGY

This is an inherited condition, characterized by an increased bulk of skeletal muscles due to the presence of a greater than normal number of muscle fibers; it is well known in many breeds of cattle but appears to be most common in the Charolais, Belgian Blue, Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep. The mode of inheritance has not been established but heterozygotes usually show some degree of muscle hypertrophy. Many of

the muscle changes are in the direction of the current demand for lean, meaty carcasses, and there is interest, especially in Europe, in the exploitation of this anomaly for meat production. Pietrain pigs (see below) exhibit many of the characteristics of double-muscled cattle, including large muscle mass and susceptibility to stress.

CLINICAL FINDINGS

Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder, an increase in the muscle:bone ratio and a decrease in body fat. Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature as is an apparent forward positioning of the tail head. Macroglossia, prognathism, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocardiographic abnormalities have been reported.[1] The condition often gives rise to dystocia, possibly due to increased gestation length, and affected females are said to be less fertile than normal.[2] There is also a very high incidence of Elso heel in affected cattle and this interferes greatly with their economic value. Other associated defects are brachygnathia and deviation of the incisor arch and, in Belgian Blue and White cattle, greater susceptibility than normal to laryngitis and bronchopneumonia.[3]

CLINICAL PATHOLOGY

Blood lactate is increased, as is susceptibility to stress. These findings are interpreted as being indicators of cell membrane fragility, which is also manifested by fragility of the erythrocytes.

NECROPSY FINDINGS

The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic, anaerobic fibers.

PIETRAIN CREEPER PIGS

A progressive muscular weakness is found in stress-susceptible Pietrain pigs. The syndrome commences with muscle tremor at 2–4 weeks of age, leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. There are no neuropathological lesions but there are myopathic changes, especially in the forelimbs.

INHERITED PROGRESSIVE MUSCULAR DYSTROPHY

This is a primary skeletal muscle disease of sheep with a strong probability of having a genetic mode of transmission.[1] It is recorded in Merino flocks in Australia and is characterized by a gradually progressive failure to flex the joints of the hindlimbs commencing at 3–4 weeks of age. Eventually the limbs are rigid at all times, and running becomes impossible. The forelimbs and the head and neck are normal. Affected sheep are easily detected when they are 1 year old and will have mobility problems by the time they are 2–3 years old. At necropsy there are pale areas in skeletal muscle and sometimes the muscles of the diaphragm in those sheep which have a tendency to bloat. The histopathology and histochemistry of the muscle lesions is comparable with that of inherited muscle atrophies in humans.[1,2]

INHERITED SPINAL MUSCULAR ATROPHY

A progressive ataxia, weakness, muscle atrophy, and recumbency develops in young calves, mostly during the first 2 weeks of life. Sensory functions are unimpaired. Some are already affected at birth and some may be stillborn. No new cases occur after 3 months of age. Conditioned by an autosomal recessive gene the defect occurs in Red Danish cattle which originated from Brown Swiss, and from German Braunvieh and American Brown Swiss. The primary lesion is degeneration of ventral horn cells of the spinal cord, without involvement of the brainstem or cerebellum. The visible lesion is the secondary atrophy of the denervated muscles.[1,2]

INHERITED SPLAYED DIGITS

Recorded only in Jersey cattle, this defect appears to be conditioned by an inherited gene; probably a monogenic autosomal recessive. Lameness becomes apparent at 2–4 months of age, the toes becoming increasingly widely spread and the toes themselves misshapen. Walking and standing are painful, especially on the front feet so that some animals graze and walk on their knees. Affected animals either lie down increasingly or stay standing for very long periods. The apparent abnormality is a defect of the muscles and ligaments holding the phalanges together.

EQUINE HYPERKALEMIC PERIODIC PARALYSIS

Synopsis

Etiology Defect in sodium channel of skeletal muscle.
Epidemiology Disease of Quarter Horses and crossbreds. Inherited as an autosomal dominant trait with variable penetrance.
Clinical signs Episodes of muscle fasciculation, stridor, muscle weakness, and flaccid paralysis.
Clinical pathology Hyperkalemia during episodes. Gene probe to detect mutated gene.
Lesions None.
Treatment Palliative. Potassium-free intravenous fluids. Acetazolamide.
Control Selective breeding. Low potassium diet.

ETIOLOGY

The disease is caused by a heritable defect in the sodium channel of skeletal muscle.[1] The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule. The disease is transmitted as an autosomal codominant with the result that homozygotes are more severely afected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

EPIDEMIOLOGY

The disease is familial and affects Quarter Horse and crossbred descendants of a single Quarter Horse sire, Impressive.[2,3] More than 50 000 registered Quarter Horses are related to known carriers of the disease.[4] Quarter Horses with the disease are presumably selected because they outperform unaffected animals in the halter classes in which they compete at horse shows,[5] although recent rule changes have changed this practice. The disease is occurs in breeds derived from or crossed with Quarter horses including Appaloosas, American Paint horses, and crossbreds.

The disease is inherited in an **autosomal codominant** manner.[1] Therefore, 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of 2 heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene.

Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease.[6] The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homozygotic animals will reach sexual maturity.

The risk of a **heterozygous** animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, while others have severe episodes starting at a young age. **Homozygous** horses are much more likely to have severe manifestations of the disease at a young age.

PATHOGENESIS

The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses.[7] This results in frequent depolarizations of individual muscle fibers causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarizations. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell, and the development of hyperkalemia.

CLINICAL SIGNS

The disease in **heterozygous** animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolapse of the third eyelid, and contraction of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor commonly noted during episodes is probably due to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in **homozygous** animals and signs of **laryngeal and pharyngeal dysfunction**, such as stridor and dysphagia, occur in almost all of these animals.[6,8] Endoscopic examination of homozygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis.[6,8] The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

Electromyographic demonstration of myotonic discharges, prolonged insertional activity, and doublets and triplets is a sensitive and specific indicator of the disease.[9]

Horses with HYPP have reduced exercise tolerance compared to normal horses.[10] Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.[11]

CLINICAL PATHOLOGY

Hyperkalemia (>5.5 mEq/L, 5.5 mmol/L) during or immediately after episodes is characteristic of the disease, although the existence of a normokalemic variant has been suggested.[12]

Diagnostic confirmation has in the past been achieved by provocative testing by administering potassium chloride (88–166 mg/kg, orally) to suspect horses.[13] However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The **test of choice** for demonstrating the presence of the mutated gene is a specific **gene probe**.[4] The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory, University of California (*www.vgl.ucdavis.edu*).

DIFFERENTIAL DIAGNOSIS

- Colic
- Laminitis
- Hypocalcemia
- Botulism
- Exertional rhabdomyolysis
- Upper airway obstruction.

NECROPSY FINDINGS

There are no characteristic findings on necropsy examination.

TREATMENT

Acute episodes

Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to **reduce the plasma potassium concentration** by intravenous infusion of isotonic, potassium free fluids such as sodium chloride, sodium bicarbonate, or dextrose. Some authors recommend infusion of calcium gluconate but others caution against its use. A practical approach is the slow intravenous administration of 0.25 to 0.5 mL of 23% calcium gluconate per kg of body weight (125–250 mL for a 500 kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose. Administration of $NaHCO_3$ at 1 mL/kg intravenously has been suggested.

Prevention of episodes

Maintaining affected horses on a **low potassium diet** reduces the frequency with which episodes occur. Alfalfa (lucerne), some oils including soyabean, molasses, lite salt (a mixture of KCl and NaCl), and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guarranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2–4 g/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.[14]

CONTROL

The disease is heritable and carriers are readily identified so a breeding program to eliminate the disease is feasible.

RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED HORSES (AZOTURIA, TYING UP, CHRONIC INTERMITTENT RHABDOMYOLYSIS)

Recurrent exertional rhabdomyolysis of Thoroughbred horses is a common dis-

ease characterized by repeated episodes of muscle disease. A similar disease occurs in Standardbred horses but its etiology and epidemiology are not well documented.

ETIOLOGY

Recurrent exertional rhabdomyolysis in Thoroughbred race horses is inherited as an autosomal dominant trait with variable expression influenced by temperament, diet, and sex.[1,2] Horses with recurrent exertional rhabdomyolysis have abnormal muscle contraction and a defect in myoplasmic calcium regulation.[3,4] These abnormalities are evident after caffeine or halothane challenge of muscle fibers from affected horses examined in vitro.[2–4] Myotubules from affected horses have higher concentrations of calcium after caffeine stimulation and muscle fibers from affected horses are more likely to contract when exposed to low concentrations of caffeine.[3] The defect does not resemble that found in the ryanodine receptor in animals with malignant hyperthermia, and there is no defect in calcium-ATPase activity or its affinity for calcium in the sarcoplasmic reticulum of Thoroughbred horses with recurrent exertional rhabdomyolysis.[5]

A genetic basis to a similar disease in Standardbreds is suspected, based on analysis of pedigree information of trotters in Sweden.[6]

EPIDEMIOLOGY

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarterhorses and related breeds, and the sporadic disease in other breeds.

The **incidence** or 1-year-period prevalence of exertional rhabdomyolysis in Thoroughbreds is 4.9–6.7% in Thoroughbred racehorses in the United States, Australia, and Great Britain, and 6.1% in National Hunt Thoroughbreds in Great Britain.[7–10] The disease occurs repeatedly in 74% of affected Thoroughbred race horses in Great Britain.[10]

Risk factors for exertional rhabdomyolysis in Thoroughbred horses, not all of which have the familial disease, include exercise, diet, use, and sex. Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or 'other' uses,[7] although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female race horses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) race horses,[7–10] and young, female Thoroughbreds are at greatest risk.[7–10] Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males.[9] Female polo ponies are not more likely to develop the disease.[11] Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or 'flighty' temperament are more likely to experience episodes of the disease.[8,12,13] Other apparent risk factors include a rest day before hard exercise,[8] feeding >4.5 kg of grain per day,[8] lameness,[8] and training gallops of shorter distance.[9] Susceptible horses consuming a high calorie diet (>30 mCal/day) with a large proportion of the calories provided by readily digestible carbohydrate, such as starch, are at increased risk of the disease.[14,15]

The disease is of considerable **economic impact** because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred race horses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease.[9,10] The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred race horses in Australia is attributable to exertional rhabdomyolysis,[16] though it is not known if all of these horses are affected by recurrent exertional rhabdomyolysis.

PATHOGENESIS

The underlying cause is described above under 'Etiology'. The disease is due to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase and carbonic annhydrase, and myoglobin. Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function.[17] Necrosis of myocytes caused pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

The release of cellular constituents results in electrolyte abnormalities, primarily hypochloremic metabolic alkalosis, systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin and, possibly, other cell constituents are nephrotoxic and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function are associated with stilted, short stepping gait.

CLINICAL FINDINGS

The cardinal feature of the disease is the occurrence of multiple episodes of rhabdomyolysis following exercise of Thoroughbred horses. Clinical findings are **variable** and range from poor performance to recumbency and death. Signs are usually mild and resolve spontaneously within 1–6 days.

The **usual presentation** is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a **short stepping gait** that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift their weight. More severely affected horses may be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk, and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent.

CLINICAL PATHOLOGY

Mildly or inapparently affected horses have moderate increases in **serum creatine kinase** (CK) (20 000–50 000 iu/L), **aspartate aminotransferase** (AST) and **lactate dehydrogenase** (LDH) activity. Severely affected horses have large increases in CK (>100 000 iu/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5–6 and 24 hours after exercise, respectively[11,18] and in the absence of further muscle damage serum AST might not return to normal levels for 7–10 days. The half-life of CK activity in serum is approximately 12 hours and in the absence of continuing muscle damage serum CK declines rapidly.[11] The persistence of increased AST activity, compared to CK, is useful in identifying affected horses days or weeks after the episode.[18]

Serum myoglobin concentrations increase markedly during exercise in affected horses, and decline within 24–48 hours.[18] Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.[12]

Severely affected horses are often **hyponatremic** (<130 mEq/L), **hyperkalemic** (>5.5 mEq/L), **hypochloremic** (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations) and **acidotic** or **alkalotic**. Hemoconcentration (hematocrit >50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration

are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used.[13] Measurement of urinary excretion or fractional excretion of electrolytes is not useful in detecting horses susceptible to recurrent exertional rhabdomyolysis.[19]

Myoglobinuria is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria. Measurement of urinary excretion of electrolytes, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of Type II (fast twitch, oxidative) fibers, mild myositis, and fibrosis.

NECROPSY FINDINGS

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle; principally, the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen, but may have a pale, streaked appearance. The kidneys are swollen and have dark brown medullary streaks. Dark brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly Type II (fast twitch, oxidative) fibers. In horses with recurrent disease there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for postmortem diagnostic confirmation

Formalin-fixed kidney and affected muscle for light microscopic examination.

DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Ear tick (*Otobius megnini*) induced muscle cramping[20]
- Polysaccharide storage myopathy of Quarter horses
- *Casia occidentalis* toxicosis
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis.

TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and laminitis, and provision of analgesia.[21]

Mildly affected horses (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2–4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate >60 bpm, rectal temperature >39°C (102°F), 8–10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any dehydration and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4–6 L every 2–3 hours). Affected horses should not be given diuretics.

Analgesia can be achieved by administration of phenylbutazone (2.2–4.4 mg/kg, IV or orally, every 12–24 hours), flunixin meglumine (1 mg/kg IV every 8 hours) or ketoprofen (2.2 mg/kg IV every 12 hours). **Mild sedation** (acepromazine or acetylpromazine 0.02–0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01–0.02 mg/kg) may decrease muscle pain and anxiety. Tranquillizers with vasodilatory activity, such as acetylpromazine, should only be given to horses that are well hydrated. Muscle relaxants, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2–4 hours. Severely affected horses should not be forced to stand.

CONTROL

Prevention centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise.

Thoroughbred race horses in training consume diets providing over 30 Mcal/day. The high energy intake is associated with increased risk of exertional rhabdomyolysis, especially if the diet provides a large (40%) of calories as readily digested carbohydrate (starch). **Diets** in which fat provides 20% of digestible energy calories and 7% as starch are associated with lower serum creatine kinase activities after exercise on a treadmill.[14] These finding have been extrapolated to provide the recommendation that race horses in training receive no more than 20% of daily digestible energy from hydrolysable carbohydrate (starch) and at least 20% of DE from fat.[22] Fat can be incorporated into the diet as rice bran, soy bean hulls, and vegetable (but not animal) fats and oils. High fat, high fiber commercial diets that are formulated for treatment of horses with polysaccharide storage myopathy or recurrent exertional myopathy are available.

Despite lack of clear evidence for a widespread role for **vitamin E or selenium** deficiency in exertional rhabdomyolysis, horses are often supplemented with 1 iu/kg of vitamin E and 2.5 µg/kg of selenium daily in the feed. Care should be taken not to induce selenium toxicosis. **Sodium bicarbonate** and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented and is suspect.[14]

Phenytoin has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6–8 mg/kg, orally, every 12 hours, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. Dantrolene (800 mg, approximately 2 mg/kg, orally 60 minutes before exercise) was demonstrated in a controlled, cross-over field trial of 77 horses, to be effective in reducing exercise-induced increases in CK and incidence of episodes of recurrent exertional rhabdomyolysis in Thoroughbred race horses.[23] Similar results were obtained in 4 horses with recurrent exertional rhabdomyolysis administered 4 mg/kg orally 90 minutes before exercise on a treadmill.[24]

Dimethylglycine, dantrolene, altrenogest and progesterone are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

PORCINE STRESS SYNDROME (PSS; MALIGNANT HYPERTHERMIA)

Synopsis

Etiology Inherited defect caused by an autosomal recessive gene at a single locus with incomplete penetrance. Also known as the halothane sensitivity gene, or PSS mutation, which is a single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.
Epidemiology Worldwide in major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. Market weight pigs, and adult sows and boars. Prevalence of defective gene varies between breeds and countries. Syndromes precipitated by stress of transportation, high environmental temperatures and humidity, exhaustive exercise, and by halothane anesthesia. Major economic importance because of deaths and poor quality pork.

Signs
- *Porcine stress syndrome:* death during transportation
- *Malignant hyperthermia:* induced by halothane anesthesia resulting in muscular rigidity and death
- *Pale, soft, exudative pork:* rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale watery pork. Dark, firm, and dry pork is variation
- *Back muscle necrosis:* reluctance to move, acute swelling and pain over back and some may die; subacute form too.

Clinical pathology Halothane test. Blood creatine kinase test. Blood typing. DNA-based test for PSS mutation gene.
Lesions Pale skeletal muscles in PSS deaths. Pale muscles in back muscle necrosis.
Diagnostic confirmation Necropsy findings. Identification of homozygous animals with tests.

Differential diagnosis list
- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

Treatment None.
Control Genetic selection. Reduction of environmental and management stressors.

ETIOLOGY

Three closely related stress syndromes occur in pigs. The **porcine stress syndrome (PSS)** is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasoconstriction and the rapid onset of rigor mortis. **Pale, soft and exudative pork (PSE)** occurs post mortem in some pigs slaughtered by conventional methods. **Malignant hyperthermia (MH)** is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle-relaxant suxamethonium. **Back muscle necrosis** of pigs is a special manifestation of the PSS.

Malignant hyperthermia also occurs in humans.[1]

PSS is caused by an inherited defect due to an autosomal recessive gene at a single locus with incomplete penetrance. It is also known as the halothane sensitivity gene, or PSS mutation, which is single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum. The PSS defect renders muscle hypersensitive to stimulation by various stressors. In stress-susceptible pigs there is a rapid onset of anaerobic glycolysis and loss of control of skeletal muscle metabolism in response to stress and anoxia.

The gene is commonly known as the *halothane-sensitivity gene* (HAL gene) because pigs with the homozygous genotype can be identified with the halothane test which results in malignant hyperthermia. The halothane gene is located within a group of blood type genes on the same chromosome allowing identification of affected pigs by blood typing. A single point mutation in the porcine gene for the skeletal muscle ryanodine receptor is associated with malignant hyperthermia in five major breeds of heavily muscled swine.[2,3] Comparison of the sequences of the HAL genes of porcine stress syndrome and normal pigs revealed a single mutation at nucleotide 1843 in the cDNA derived from the HAL gene.[2] The literature on the causative mutation for the porcine stress syndrome has been reviewed.[4]

EPIDEMIOLOGY

Prevalence and occurrence

This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior quality meat is due to genetics (halothane positive) with the remainder being due to pre-slaughter and post-slaughter treatment.[5]

PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations. The halothane test and the creatine kinase (CK) test are useful for this purpose. A DNA-based test with 99% accuracy is also available.[6] Surveys in the UK found that the prevalence in the British Landrace varies from 0 to 23% of herds with an average of 11%. In European breeds, the prevalence varies from 0 to 88% with up to 100% in the Pietrain breed. None is present in the Large White breed although one isolated report describes malignant hyperthermia in a single Large White pig. The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark.[7] Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10 245 breeding swine of various breeds from 129 farms in the US, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous.[6] The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively. The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30–75% lower in Canadian swine than in US swine, with the exception of Yorkshires, for which the

gene frequency is threefold in Canadian swine.[6]

Risk factors

Animal risk factors

Susceptibility to the PSS is inherited and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace where a score for muscling as well as growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences in that halothane stress susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshires, Danish Landrace, and Duroc boars.[8]

There is a **correlation between halothane susceptibility and carcass traits**. Halothane status is the most important factor influencing pork quality, although pre-slaughter handling and stunning method also influence the carcass quality.[9,10]

Halothane-positive animals usually score higher for visual conformation of the loin and ham than pigs which are halothane-negative. The progeny of reactor boars are also more susceptible than the progeny of non-reactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs which are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs where it is likely to cause poor carcass quality.

The **gene for the porcine calcium channel** has been sequenced and the site of the causative mutation located.[2] The mutation was found in 5 major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. The prevalence of the gene in certain breeds in North America and England is given above.

Landrace pigs can be divided into those which are sensitive to halothane and develop pale, soft, exudative pork post mortem, those which are resistant to halothane but develop pale, soft, exudative pork, and those resistant to halothane and pale, soft, exudative pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and pale, soft, exudative pork has significantly higher glucose-6-phosphate levels and lower phosphocreatine under thiopentone anesthesia than muscle from pigs susceptible to PSE and normal pigs. Altered muscle fiber type is not the primary basis of the disease complex.

Environmental and management risk factors

The most important precipitating factors are **transportation at high environmental temperatures and humidity, exhaustive exercise**, and under experimental conditions, the more specific reaction towards the **anesthetic halothane**. Response of pigs to transport is dependent on genotype particularly at high temperatures such as **36°C**.[11] Experimentally, psychological mechanisms can precipitate the PSS. The effects of mixing, transportation, and duration of lairage can have profound effects on carcass characteristics of susceptible pigs. Death during transportation and PSE are associated with fear, defensive or aggressive reactions in unfamiliar social environments, or conflict with other strange pigs or man. Other activities which may trigger malignant hyperthermia include restraint, mating, farrowing, fighting, and vigorous exercising.

Economic importance

The economic losses associated with the PSS are due to mortality from transport death and inferior meat quality due to pale, soft, exudative pork. As a result of the excessive rates of production of lactic acid and heat, sarcoplasmic proteins denature, thereby causing a deterioration of the water-binding capacity of muscle. The increased osmotic activity due to end-products of hypermetabolism causes an influx of water from the extracellular space resulting in hemoconcentration and increased intramyofiber water content. The muscle becomes pale, soft, and exudative, sour-smelling and loose-textured. The shrinkage due to water loss during storage, transport and processing of the carcass is the major cause of wholesale losses at pork packing plants. PSE carcasses yield less bacon and the drip loss from fresh PSE meat is more than doubled compared to normal carcasses. Another cause of lost revenue with malignant hyperthermia susceptible swine is their decreased average daily weight gains, conception rates, litter sizes, and boar breeding performance.

Pathogenesis

The molecular basis for susceptibility to the PSS is a hypersensitive triggering mechanism of the calcium-release channel of skeletal muscle sarcoplasmic reticulum.[6] The calcium channel, also known as the ryanodine receptor, plays a critical role in the initiation of muscle contraction. The PSS defect renders muscle hypersensitive to stimulation by various stressors. Stress-susceptible pigs cannot tolerate stress and lose control of skeletal muscle metabolism. The stress may be from external influences such as transportation, fear and excitement, or halothane anesthesia. There is excessive catecholamine release and the sudden onset of anaerobic glycolysis of skeletal muscle, excessive production of lactate and excessive heat production which, in conjunction with peripheral vasoconstriction, leads to hyperthermia. Following exertional or thermal stress, susceptible pigs undergo more extensive physiological change than do resistant pigs. Halothane sensitive pigs are more susceptible to becoming non-ambulatory and when subjected to multiple stressors and may be more prone to producing inferior pork products.[10] The blood glucose concentrations are dependent on the malignant hyperthermia genotype; the homozygous positive animals having the highest levels and the homozygous negative animals having the lowest.[12] The changes in carbohydrate metabolism at rest in malignant hyperthermia positive animals are caused by latent increases of intracellular Ca^{2+} concentrations. Under physical load conditions there is higher lipolysis which may be the result of an indirect activation of the lipolytic system via catecholamine induced cAMP turn-over.

Depending upon the nature, severity, and duration of the stress, the syndrome may manifest in different ways:

- The **porcine stress syndrome** causes rapid death following severe stress.
- The **pale, soft, and exudative (PSE) pork** and **dark, firm, dry (DFD) pork** are seen after slaughter which may have been preceded by mild stressors during lairage
- The **malignant hyperthermia** is drug-induced.

Pale, soft, exudative pork is attributed to increased glycolysis after slaughter. In muscles which develop **dark, firm, dry pork**, the muscle glycogen is already depleted before slaughter.[13] When PSE develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.[13]

Malignant hyperthermia is the drug-induced, often fatal, stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a

mixture of halothane and oxygen.[14] Susceptible pigs develop limb rigidity and a hyperthermia which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent Ca^{2+} accumulation by sarcoplasmic reticulum and/or the mitochondria with a rise in myoplasmic concentration of Ca^{2+} and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histomorphometric evidence of cardiac abnormalities in malignant hyperthermia susceptible pigs.[15] The mitochondria from predominantly red muscle fibers have a greater calcium binding capacity than those from predominantly white muscle fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis and a rise in the creatine kinase activity and concentration of potassium, lactate, glucose, free fatty acids and catecholamines in blood. There is a large release of glucose and potassium from the liver which contributes to the hyperglycemia and hyperkalemia. There is a marked α-adrenergic stimulation which is responsible for the heat production in malignant hyperthermia susceptible pigs. However, the β-adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent.[16] The lactic acidemia is severe due to the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoflurane and enflurane, and succinylcholine.

Exposing stress-susceptible pigs to halothane or exercise induces glycolysis but the mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

CLINICAL FINDINGS

Porcine stress syndrome (transport death)

Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period.[17] If seen alive, affected pigs initially show a rapid tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterwards and the total time course of the syndrome is generally of the order of 4–6 minutes.

Malignant hyperthermia

Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by anesthesia with potent volatile anesthetics such as halothane or by the administration of succinylcholine. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, and a marked increase in basal metabolic rate, increased oxygen consumption, carbon dioxide production and severe hyperthermia and tachycardia, tachyarrhythmia and death. Once fully developed the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in man. It has also been used as a method for determining stress susceptibility for genetic selection programs.

Pale, soft, and exudative pork (PSE)

In stress-susceptible pigs, after slaughter, the inferior quality of the meat with its pale, soft, exudative characteristics is obvious. This is due to excessive postmortem glycolysis with lactic acid production and a rapid fall in muscle pH with depigmentation and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter, but then decreases so that affected carcasses have been 'set' and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41°C (106°F) or greater 45 minutes after slaughter, compared to the normal pork with a pH above 6 and a temperature less than 40°C (104°F). This causes denaturation of muscle proteins leading to affected meat which has inferior taste, cooking and processing qualities, and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling prior to and during slaughter, and this aspect of the syndrome is of major economic importance.[9,18,19] Rapid chilling helps prevent PSE but chill type has no effect.[20]

Dark, firm, and dry pork (DFD)

Dark, firm, dry pork has darker color and higher ultimate pH than normal meat. In muscles which develop DFD the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

Back muscle necrosis

Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

CLINICAL PATHOLOGY

Several testing methods are available for predicting susceptibility.

Halothane test

The halothane test is highly reliable for the identification of pigs which are homozygous for the single recessive gene responsible for susceptibility to the PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous malignant hyperthermic susceptible pigs react by developing limb rigidity). Penetrance of the halothane sensitivity trait is estimated to vary from 50 to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and will not identify all the pigs which will develop PSE. There is now evidence that it will detect the heterozygote.[21] Stress-susceptible pigs are sensitive to halothane at 8 weeks of age and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminant hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals which do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE.

However, there may be breed variations as mentioned above.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the in vivo ^{31}P nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets.[22] Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.[7]

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic which binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathological animals and may be a useful adjunct to the halothane test.

Blood creatine kinase levels

The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test and blood samples taken 8–24 hours later and analyzed for CK. The original work indicated a good correlation between the CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs which develop PSE have increased serum levels of CK. Increased CK activity is highest in stress-susceptible pigs of a certain phenotype Phi-B, and their total plasma CK levels are higher than non-reactors.[23] The initial test was modified so that blood could be collected as drops on a filter paper and sent to a laboratory for identification by a bioluminescent technique. A recent evaluation of a commercial CK screening test using the method of bioluminescence compared with the halothane challenge test on young boars entering a Record of Performance Test Station revealed that it was an inadequate indicator of susceptibility to the PSS or MH. In a different study the CK levels of piglets 8–10 weeks of age predicted halothane-induced stress syndrome with an accuracy of 87–91%.

Plasma pyruvate kinase activity has been compared with CK activity as indicators of the PSS. Both enzymes are increased significantly in homozygous halothane-reacting pigs compared to non-reacting pigs. Pyruvate kinase activity was less variable within groups than CK activity which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

Blood typing

Blood typing is also used as a method for the identification of susceptible pigs. On one of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphoferose isomerase (PHI). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus, blood grouping may be used to detect halothane-sensitive pigs as well as heterozygote carriers.

A DNA-based blood test can now be used to detect the HAL gene status.[2,3] It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50 µL of blood. The test is more than 99% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries.[6] A recent study showed that 23% of pigs classified as Hal-1843 free based on a DNA test responded abnormally to halothane anesthesia.[24]

Pale, soft, and exudative pork

This is evaluated by a meat quality index which combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from Mm longissimus dorsi muscle exhibit a rate of Ca^{2+} efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies towards it, which restricts their value in breeding programs.

Erythrocyte osmotic fragility

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.[21]

Other tests

Any reliable test which can identify stress-susceptible pigs without using halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS.[25] Differences in the levels of cortisol, creatinine, aspartate aminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.[26]

An allele specific PCR (AS-PCR) technique has been developed.[27] A PCR followed by reduction endonuclease assay has been developed and used[28] on plucked hair as a source of genomic DNA. In a test with this method 9 of 12 Pietrains were tested homozygous or heterozygous. A one-step procedure has been developed called mutagenically separated PCR (MS-PCR).[29]

NECROPSY FINDINGS

In the PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested and there is usually an increased quantity of pericardial fluid as well as pulmonary congestion and edema. The muscles – especially the gluteus medius, biceps femoris, and longissimus dorsi – are pale, wet, and soft. In back muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal, and are easily obscured by autolysis. In some instances only interstitial edema is visible while in animals which have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly-sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

Samples for confirmation of diagnosis

- **Genetic analysis** – 50 g frozen muscle (DNA ANALYSIS) and hair for PCR tests.
- **Histology** – formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM).
- **Biochemistry** – it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis[30] which is manifested as lower values of acid–base excess and HCO_3 – with higher H^+ concentrations and pCO_2 than resistant pigs.

DIFFERENTIAL DIAGNOSIS

The acute nature of the PSS and its relation to stress serve to differentiate it from most other syndromes causing sudden death in market and adult sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death including intestinal volvulus, heat exhaustion, suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency can produce a similar clinical syndrome
- Porcine viral encephalomyelitis may also result in a similar clinical syndrome in postweaned pigs. Pathological and biochemical examinations differentiate these from the PSS.

TREATMENT

The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention.[9] The therapeutic dose is 7.5 mg/kg BW. Carazolol is effective for the prevention of transport death when given 3–8 hours before transportation and improves meat quality compared to untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell membrane integrity.

CONTROL

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

Genetic selection

The best strategy for control of this complex is not clear.[6] Several factors must be considered. Swine homozygous for the PSS mutation are at very high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine which are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if during marketing and slaughter the environmental and management risk factors which precipitate PSE are minimized. The mutation is not a prerequisite for leanness and muscularity and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known.[31] However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression finely controlled in a breeding program.

The various testing methods described under clinical pathology are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify it will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.[2]

Management of stressors

Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of pale, soft, exudative meat characteristics are a significant economic problem in some countries. The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spray-cooling of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir but should be rested for at least 1–2 hours if they have been stressed only by transportation. In cases of severe physical exertion even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum and transport should be avoided on excessively hot days.

Inherited defects of the skin

INHERITED SYMMETRICAL ALOPECIA

This is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetrical and commences on the head, neck, back, and hindquarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.

INHERITED CONGENITAL HYPOTRICHOSIS

In this congenital disease there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in **pigs**, in which it is associated with low birth weights, weakness, and high mortality, and in Poll Dorset **sheep**, in which the face, ears, and lower legs are bald, there are no eyelashes, and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.[1]

Viable hypotrichosis

The condition is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair is completely absent from most of the body at birth but eyelashes and tactile hair are present about the feet and head. Occasionally hair may be present in varying amounts at birth but is lost soon afterwards. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on section no hair follicles are present in the skin. The condition is inherited as a single, recessive character.

Congenital hypotrichosis has been reported in a Perheron draught horse.[2] At birth there were circumscribed patchy areas alopecia which was progressive becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia and the animal was still alive at 6 years of age.

Non-viable hypotrichosis

This is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

Hypotrichosis with anodontia

Congenital X-linked hypotrichosis with missing teeth in cattle is characterized by abnormal morphogenesis to teeth, hair follicles, and eccrine sweat glands.[3] Two different forms can be distinguished according to the severity of the tooth defects: (1) congenital hypotrichosis with complete or almost complete anodontia; (2) congenital hypotrichosis with completely missing incisors or defective incisors. Impaired body condition and growth of the affected animals result from missing teeth. In addition, animals with sparse hair are more susceptible to cold and more prone to skin lesions.

The phenotype and inheritance of hypotrichosis with nearly complete anodontia has been recorded in pedigreed German Holstein calves.[3] The phenotype is inherited as a monogenic X-linked recessive trait. A reverse transcription-PCR assay was used to identify the causative large genomic deletion in the bovine *EDI* gene. The *EDI* gene for the hypotrichosis and anodontia phenotype appears to have pleotropic effects on hair follicles, eccrine nasolabial glands, apocrine sweat glands, individually expressed contours of the muzzle, and on development of incisor and premolar/molar teeth. A molecular genetic test for the pathological mutation allows the unequivocal classification of animals with congenital hypotrichosis and anodontia and identification of heterozygous carriers and their exclusion from further breeding.[3]

Streaked hairlessness

A sex-linked semidominant gene causes development of a streaked hairlessness in which irregular narrow streaks of hypotrichosis occur in female Holsteins.

Partial hypotrichosis

Recorded in polled and horned Hereford cattle. At birth there is a fine coat of short, curly hair which later is added to by the appearance of some very coarse, wiry hair. The calves survive but do not grow well. The character is inherited as a simple recessive. The disease in Poll Herefords has the same short curly coat but there is also a deficiency of hair in the switch, and over the poll, brisket, neck, and legs in some cattle. Some have a much lighter hair coat color. Histologically there is a characteristic accumulation of large trichohyaline granules in the hair follicles.

Rat tail syndrome in calves

The 'rat tail' occurred following the importation of continental European breeds of cattle into the United States when those breeds were crossed with Angus or Holsteins.[4] The abnormality is characterized by short, curly, malformed, sometimes sparse hair and lack of normal tail switch development. Histologically, there are enlarged, irregularly distribute, and clumped melanin granules in the hair shafts, which are asymmetrical, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas. A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding.[4] The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. The syndrome is controlled by interacting genes at 2 loci. Cattle which express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus I

INHERITED HAIR COAT-COLOR-LINKED FOLLICLE DYSPLASIA

Some **'buckskin'-colored follicular dysplasia** occurs in so-called 'Portugese' Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal dominant inheritance.[1]

A **black hair colored follicular dysplasia** is also recorded in Holstein cattle.[2] Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described.[3] Adult onset alopecia occurred and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

INHERITED BIRTHCOAT RETENTION

This is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medullated fibers in contrast with the non-medullated wool fibers of the normal sheep fleece.

INHERITED LEUKODERMA

The **Arab fading syndrome** commences in young horses in particular families of Arab horses as round, unpigmented patches of skin around the lips, eyes, perineum, preputial orifice. Some cases recover spontaneously but the blemish is usually permanent.

INHERITED ALBINISM AND LETHAL WHITE FOAL SYNDROMES

Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete or partial or incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytopenic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings which occur on horses are localized forms of piebaldism. Generalized and complete albino animals (oculocutaneous albinism) have white hair, white skin, pink irides and usually exhibit photophobia.[2] Generalized albinism in the horse is inherited as autosomal dominant trait which is only viable in the heterozygous states. These horses have incomplete albinism as there is some coloration to the iris. Matings of heterozygous albino horses produce a nonviable embryo 25% of the time which is resorbed in gestation. This is one form of lethal white foal syndrome. A second form of lethal white foal syndrome is an autosomal recessive defect which occurs by mating of overo paint horses. Lethal white foals from such breedings are characterized by albinism and congenital defects of the intestinal tract.

INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)

This is a lethal defect of Holstein-Friesian calves inherited as an autosomal recessive character. The calves, most commonly heifers, are normal at birth but at 1–2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and folded skin especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immovable. There is usually alopecia about the base of the ears and eyes. The tips of the ears are curled backwards. The horns fail to develop and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuffling, restricted gait. Calves assume a recumbent posture for most of the time. Severe emaciation leads to destruction at about 6 months of age.

Histological changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.[1]

INHERITED CONGENITAL ABSENCE OF THE SKIN

Classical epitheliogenesis imperfecta

Absence of mucous membrane, or more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs,[1] and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In **cattle** the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein-Friesians, but is also recorded in Japanese Black, Shorthorn, Sahiwal,[2] and Angus cattle. In **pigs** the skinless areas are seen on the flanks, sides, back, and other parts of the body. The defect is usually incompatible with life and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single recessive gene. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.[3]

Familial acantholysis

Suspected of being inherited, this defect in Angus calves is characterized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at carpal and metacarpophalangeal joints and coronet, and there is separation of horn at the coronet.

Epidermolysis bullosa

This congenital disease of Suffolk and South Dorset Down sheep[4] and Simmental[5] and Brangus calves is characterized by the formation of epidermal bullae in the mouth and on exposed areas of skin, such as the extremities of the limbs, the muzzles and ears, leading to shedding of the covering surface and separation of the horn from the coronet. Lesions may be present at birth. Simmental calves grow poorly, have hypotrichosis, and suffer repeated breaks in the skin, apparently due to an abnormal susceptibility to trauma. Most calves die but some survive and the lesions subside. In Simmentals the disease is inherited as an autosomal dominant trait. The disease in Brangus calves is very similar to familial acantholysis in Angus cattle.

The severe form of Herlitz junctional epidermolysis bullosa, which occurs in humans has been recorded in foals of the French draft horse breeds.[6] A mutation in the *LAMC2* gene is responsible for the defect. Affected foals were born with skin blistering, skin and buccal ulceration followed by loss of hooves. In the affected skin there was disjunction of the epidermis from the underlying dermis at the dermal-epidermal junction. Genomic DNA testing is used to determine the presence of the mutation in carrier animals.

Hereditary junctional mechanobullous disease

This defect is inherited in Belgian foals, Angus and Simmental calves, and Suffolk and South Dorset Down lambs.[7,8] It is usually recorded under the heading of epidermolysis bullosa. There may be no shedding of skin but the initial bullous lesions at the coronet, considered to be initiated by abrasions, lead to sloughing of the hooves.

Red foot disease of sheep

This is similar to both of the above diseases. It is recorded in Scottish Blackface and Welsh mountain[9] sheep. The lesions are not present at birth but become apparent at 2–4 days of age when there is sloughing of skin of the limbs, the accessory digits, the ear pinna, and of the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached exposing the red corium below, hence 'red foot'. The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown there are indications that it is inherited.

INHERITED CROP EARS

Inherited as a single autosomal, incomplete dominant character in Bavarian Highland cattle, this anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.[1]

INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California.[1] It is inherited as an autosomal recessive trait.

Liver insufficiency is present but the liver is histologically normal. Phylloerythrin and bilirubin excretion by the liver is impeded and the accumulation of phylloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die from renal failure associated with progressive fibrosis of the kidney.

A similar disease in Corriedale sheep in California is inherited as an autosomal recessive trait.[1] The functional defect is not in the uptake of unconjugated bilirubin and phylloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with some shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight, working in concert with the inborn error of metabolism to induce photosensitization.[1]

INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASE)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless and the skin is covered with thick, horny scales separated by fissures which follow the wrinkle lines of the skin.[2] These may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable and, although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result form the influence of a single recessive gene.

INHERITED DERMATOSIS VEGETANS

This disease appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3 weeks of age. The lesions occur at the coronets and on the skin.[3] Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die but some appear to recover completely. Many of the deaths appear to be due to the giant-cell pneumonitis which is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect which selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

This is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, horses, in Finnish and White Dorper[1] sheep, and a mild form is seen in Merino sheep. The latter is inherited as a simple autosomal recessive. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of papyraceous scars are also characteristic. Pieces of skin may be ripped off when affected sheep are being handled. In horses the skin in some parts of the body is thinner than elsewhere, e.g. the skin of the ventral abdomen and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein,[2] and is related to a recognized problem in dogs and cats identified as 'dominant collagen packing defect'.[3]

Hereditary equine regional dermal asthenia has been recorded in related Quarter horses in Brazil similar to that reported in the United States.[4] Reported cases of horses with hyperextensible skin have involved Quarter Horses.[5] Clinically there were bilateral asymmetrical lesions of the trunk and lumbar regions, where the skin was hyperextensible. Handling of the skin elicited a painful response and superficial trauma led to skin wounds. The skin was thinner than normal in affected areas, with thickened borders and harder fibrotic masses. Histologically, the collagen fibrils were thinner and smaller, which created a loose arrangement of collagen fibers within the deep dermis. The deep dermis contains a distinctive horizontal linear zone in which separation of collagen bundles results in formation of large empty cleft-like spaces between the upper and lower regions of the deep dermis: 'zonal dermal separation'.[5] Pedigree analysis indicates an autosomal recessive type of inheritance.

The Ehlers–Danlos syndrome, recorded in Charolais and Simmental cattle, and Rippolesa sheep,[6] is also characterized by extreme fragility of skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers.

The syndrome has also been recorded in lambs.[7] The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of epidermis from dermis with blood-filled cavitations and intact skin which can be easily torn.

INHERITED MELANOMA

Inherited cutaneous malignant melanoma are found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of them associated with the swine major histocompatibility complex.[1] Familial melanoma have also been recorded in members of successive litters from an individual Duroc x Slovak White sow.[2]

INHERITED HYPERHIDROSIS

A condition characterized by excessive sweating, and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

Miscellaneous inherited defects

INHERITED EYE DEFECTS

An inherited, congenital **corneal opacity** occurs in Holstein cattle. The cornea is a cloudy blue color at birth and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

With **lens dystrophy** Brown Swiss cattle are affected by an inherited congenital blindness with a cloudy shrunken lens as the cause. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Bilateral **cataract** has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal dominant and can be eradicated easily by culling.

Complete **absence of the iris** (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataract at about 2 months of age. Total **absence of the retina** in foals has also been recorded as being inherited in a recessive manner.

Microphthalmia is reported to be an inherited defect in Texel sheep, but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe.[1,2] Following importation and 'breeding up' of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand and an experimental breeding flock is maintained to study the molecular genetics.[3] It is inherited as an autosomal recessive trait. An outbreak in Texel sheep in New Zealand has been recorded.[1] The optic globes are approximately one half normal size and the optic nerves at the chiasma are approximately one half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole, and connected to the optic nerve posteriorly by a short stalk.[1] The morphology and morphogenesis of the defect has been followed in embryos at different ages from ewes known to be carriers of the microphthalmia factor.[2] The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

Typical colobomata, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects they should be named in certificates of health but they are not usually considered as being a reason for disqualification from breeding programs. In Charolais cattle the inheritance of the defect is via an autosomal dominant gene with complete penetrance in males and partial (52%) penetrance in females. The prevalence may be as high as 6% and in most cases both eyes are affected. The defect is due to incomplete closure of one of the ocular structures at or near the line of the embryonic choroidal fissure. Failure of the fissue to close represents the beginnings of the coloboma. The retina, choroid, and sclera are usually all involved.

Entropion is inherited in a number of sheep breeds including Oxfords, Hampshires, and Suffolks. Affected lambs are not observed until about 3 weeks of age when attention is drawn to the eyelids of the apparent conjunctivitis. A temporary blindness results but even without treatment there is a marked improvement in the eyelids and the lambs do not appear to suffer any permanent harm.

Ocular dermoids are recorded as genetically transmitted in Hereford cattle. They occur as multiple small masses of dystrophic skin complete with hair on the conjunctiva of both eyes of affected cattle. They can be anywhere on the cornea, on the third eyelid, or the eyelid and may completely replace the cornea; there may be a resulting marked dysplasia of the internal ocular structures.

Combined ocular defects

Although the vision appears unaffected a large number of congenital defects of the eye have been observed in cattle, including Herefords, affected by partial albinism. The defects include iridal heterochromia, tapetum fibrosum, and colobomas. Congenital blindness is also seen in cattle with white coat color, especially Shorthorns. The lesions are multiple and include retinal detachment, cataract, microphthalmia, persistent pupillary membrane, and vitreous hemorrhage. Internal hydrocephalus is present in some, and hypoplasia of optic nerves also occurs.

A combination of **iridal hypoplasia, limbic dermoids and cataracts** was recorded in the eyes of progeny of a Quarter Horse stallion, presumably as a result of a mutation in the stallion and transmission to the foals via an autosomal, dominant gene.[4] The inheritance is a simple autosomal recessive.

Iridiremia (total or partial absence of iris), **microphakia** (smallness of the lens), ectopia lentis and cataract have been reported to occur together in Jersey calves. The mode of inheritance of the characters is as a simple recessive. The calves are almost completely blind but are normal in other respects and can be reared satisfactorily if they are hand-fed. Although the condition has been recorded only in Jerseys, similar defects, possibly inherited, have also been seen in Holsteins and Shorthorns.

Inherited night blindness occurs in Appaloosa horses which have otherwise normal sight. No defect has been described in the eyes.

INHERITED PROLONGED GESTATION (ADENOHYPOPHYSEAL HYPOPLASIA)

Prolonged gestation occurs in cattle and sheep in several forms and is usually, although not always, inherited. The two recorded forms of the disease are prolonged gestation with fetal giantism and prolonged gestation with deformed or normal or small size fetuses.

Prolonged gestation with fetal giantism

The inherited disease is recorded in Holstein, Ayrshire, and Swedish cattle with prolongation of pregnancy from 3 weeks to 5 months. The cows may show marked abdominal distension but in most cases the abdomens are smaller than one would expect. Parturition, when it commences, is without preparation. Udder enlargement, relaxation of the pelvic ligaments, and loosening and swelling of the vulva do not occur and there is also poor relaxation of the cervix and a deficiency of cervical mucus.[1] Dystocia is usual and cesarean section is advisable in Holstein cattle but the Ayrshire calves have all been reported as having been born without assistance. The calves are very large (48–80 kg body weight) and show other evidence of post-term growth, with a luxuriant hair coat and large, well-erupted teeth which are loose in their alveoli, but the birth weight is not directly related to the length of the gestation period.

The calves exhibit a labored respiration with diaphragmatic movements more evident than movements of the chest wall. They invariably die within a few hours in a hypoglycemic coma. At necropsy there is adenohypophyseal hypoplasia and hypoplasia of the adrenal cortex and the thyroid gland. The progesterone level in the peripheral blood of cows bearing affected calves does not fall before term as it does in normal cows.

Prolonged gestation with craniofacial deformity

This form of the disease has been observed in Guernsey, Jersey, and Ayrshire cattle. It differs from the previous form in that the fetuses are dead on delivery, show gross deformity of the head, and are smaller than the normal calves of these breeds born at term. In Guernseys the defect has been shown to be inherited as a single recessive character and it is probable that the same is true in Jerseys. The gestation period varies widely with a mean of 401 days.

Clinical examination of the dams carrying defective calves suggests that no development of the calf or placenta occurs after the seventh month of pregnancy. Death of the fetus is followed in 1–2 weeks by parturition unaccompanied by relaxation of the pelvic ligaments or vulva or by external signs of labor. The calf can usually be removed by forced traction because of its small size. Mammary gland enlargement does not occur until after parturition.

The calves are small and suffer varying degrees of hypotrichosis. There is hydrocephalus and in some cases distension of the gut and abdomen due to atresia of the jejunum. The bones are immature and the limbs are short. Abnormalities of the face include cyclopian eyes, microphthalmia, absence of the maxilla, and the presence of only one nostril. At **necropsy** there is partial or complete aplasia of the adenohypophysis. The neural stalk is present and extends to below the diaphragm sellae. Brain abnormalities vary from fusion of the cerebral hemispheres to moderate hydrocephalus. The other endocrine glands are also small and hypoplastic.

The disease has been produced experimentally in ewes by severe ablation of the pituitary gland, or destruction of the hypothalamus, or section of the pituitary stalk in the fetus and by adrenalectomy of the lamb or kid. Infusion of ACTH into ewes with prolonged gestation due to pituitary damage produces parturition but not if the ewes have been adrenalectomized beforehand.

Prolonged gestation with arthrogryposis

A form of prolonged gestation, which occurs in Hereford cattle and is thought to be inherited, is accompanied by arthrogryposis, scoliosis, torticollis, kyphosis, and cleft palate.

INHERITED COMBINED IMMUNODEFICIENCY (CID) IN FOALS OF ARABIAN BREEDING

Synopsis

Etiology Inherited immunodeficiency in foals of Arabian parentage caused by a mutation in the gene coding for DNA-protein kinase catalytic subunit.
Epidemiology Familial pattern of occurrence with autosommal recessive inheritance. Approximately 8% of Arabian horses are heterozygous for the mutation (carriers). Random mating results in approximately 1 in 600 foals being affected, but not all matings are random and the incidence of the disease is less than this number.
Clinical findings Foals normal at birth but succumb to systemic infection soon after birth and die before 3 months of age. Death from acute septicemia, or recurrent or chronic continuous infection, usually of respiratory tract. Poor response to normally effective antibiotic therapy.
Clinical pathology Lymphopenia, hypogammaglobulinemia. PCR test detects animals heterozygous (carriers, parents of affected foals) or homozygous (affected foals) for the mutated gene.
Necropsy findings Thymic, lymph node, and splenic hypoplasia and a marked reduction in the numbers of splenic and lymph node lymphocytes.
Diagnostic confirmation. PCR detection of mutated gene (homozygouse in affected foals). Lymphopenia and agammaglobulinemia in a foal of Arabian breeding.
Treatment Nil.
Control Ideally, elimination of the mutated gene by not breeding carrier animals. The disease can be prevented by not breeding a carrier animal to another carrier.

ETIOLOGY

The fundamental defect is a 5 base-pair deletion in the specific gene that codes for DNA-dependent protein kinase.[1–3] The gene is located on chromosome ECA9.[4] This mutation causes a lack of activity of the catalytic subunit of DNA-dependent protein kinase.[1,2,3] The deficiency of protein kinase activity, which is absolute in affected foals, results in the inability to join DNA strands that have been broken as part of the normal process of creation of V (variable) regions of T cell and B cell antigen receptors on lymphocytes. Without these receptors the lymphocytes are unable to respond to antigens and thus the foal is not capable of mounting adaptive, either cellular or humoral (antibody), immune responses.[1]

EPIDEMIOLOGY

The immunodeficiency is inherited as an autosomal recessive defect. The disease occurs in purebred and part-Arabian horses. It has also occurred in an Appaloosa foal that had an Arab stallion in the fifth past generation of its mother's pedigree. In one survey of Arabian foals in the United States, the prevalence rate of affected foals was 2.3% of 257 foals of Arabian breeding, and 25.7% of the parents of affected foals were estimated to be carriers of the genetic defect.[5] However, this likely represents an overestimation of the incidence of the disease and prevalence of the mutation in the population of Arabian horses because of selective testing.[6] The frequency of carriers of the mutation for severe combined immunodeficiency is approximately 8%, with an estimated 0.2% (1 in 600) of foals of random matings between Arabian horses affected with the disease, based on

a survey of 250 horses.[6] Approximately 17% of Arabian horses are heterozygous for the mutation and 0.3% of foals are homozygous among > 6000 horses tested by a commercial laboratory.[7]

Affected foals usually appear normal at birth, but are highly susceptible to infections from 2 to 65 days after birth and usually die from one or more infections by 3 months of age. The sires and dams of affected foals are clinically normal and have normal lymphocyte counts and serum immunoglobulin concentrations.

PATHOGENESIS

Affected foals are born with a combined immunodeficiency associated with a deficiency in both B-lymphocytes (which produce immunoglobulins) and T-lymphocytes (which provide cellular immunity). There is a marked lymphopenia and failure of immunoglobulin (Ig) synthesis and absence of delayed hypersensitivity of skin responses. Foals that receive immunoglobulins from the dam's colostrum derive passive immunity and can survive for as long as 4 months. Foals that do not receive colostrum die much earlier. The cause of death is infectious disease.

Affected foals are susceptible to infections of all kinds, but mostly of the respiratory tract. Adenoviral pneumonia is considered to be the most common secondary complication, probably because adenovirus infection is so widespread in the horse population. Affected foals may also die from hepatitis, enteritis, or infection of other organs without pulmonary involvement. While adenoviral pneumonia is the most common complication, infections with bacteria and *Pneumocystis carinii* also occur. *Cryptosporidium* sp. has also been recorded in a number of foals with diarrhea, which is also a common complication.

CLINICAL FINDINGS

Affected foals usually become ill from 10 to 35 days of age. Commonly there is a history suggesting a mild disease of the respiratory tract, especially the appearance of a bilateral nasal discharge, which often becomes sufficiently thick to interfere with sucking. The foal is unthrifty, lethargic, and tires easily but still nurses and eats solid feed. A deep dry cough and a serous to mucopurulent ocular and nasal discharge are common when pneumonia is present. There is moderate fever (39.5°C, 103°F) and an increase in the heart and respiratory rates. The depth of respirations is increased and a double expiratory effort is common. On auscultation, loud bronchial tones and moist and dry crackles are common over the anterior ventral aspects of both lungs. A chronic diarrhea is present in some foals, and alopecia and dermatitis, commonly associated with an infection by *Dermatophilus congolensis*, also occur. An important clinical feature is that affected foals do not respond favorably to treatment with antimicrobial agents. The course of the illness will vary from a few days to a few weeks and probably depends on the degree of immunodeficiency and the nature of the infection. Most affected foals become progressively worse over a period of 2–4 weeks, and death by 3 months of age is the usual outcome.

CLINICAL PATHOLOGY

Lymphopenia is a constant finding with counts often less than 1000/mL and there is a concurrent hypogammaglobulinemia in foals that have not received colostrum. There is no IgM in precolostral serum of the foal. Following ingestion of colostrum, all subclasses of immunoglobulin will be present but in affected foals the level of IgM will steadily decrease weekly until at about 36 days when IgM is detectable. The lack of IgM is because of lack of synthesis and the shorter half life of this isotype of immunoglobulin in foals – serum IgG concentrations decline more slowly. Until the development of the PCR test for detection of homozygous foals and confirmation of the disease, the measurement of serum Ig concentrations was considered essential for a definitive diagnosis. Additional tests include enumeration of B-lymphocyte and T-lymphocyte responses to phytolectin stimulation and other tests of lymphocytic immunological function, but these tests are no longer required for diagnostic confirmation of the disease.

NECROPSY FINDINGS

The lymph nodes are small and splenic follicles are not visible. A viral interstitial pneumonia and a secondary bacterial bronchopneumonia are common. The thymus gland is usually hypoplastic. Histologically the lymph nodes and spleen are depleted of lymphocytes, and germinal centers are absent. In some foals there are foci of necrosis of the intestinal epithelium but with minimal infiltration of inflammatory cells. Inclusion bodies of adenovirus may be present in the cells of several different body systems. In Australian foals *Rhodococcus equi* can be commonly isolated from pulmonary abscesses. Additional histological findings include a severe adenoviral pancreatitis and adenitis of the salivary glands.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation in an apparently chronic case of pneumonia in a young foal depends on the identification of the characteristic lymphopenia.

The differential diagnosis list includes:

- Septicemia and pneumonia of foals, caused by *Rhodococcus equi*
- Agammaglobulinemia due to failure of transfer of maternal immunoglobulins from colostrum. In many foal populations as many as 20% of foals are immunodeficient for this reason
- Other immunodeficiencies (Table 35.1). Foals with these deficits are very susceptible to a variety of infectious diseases and are usually chronically ill, most often with respiratory infections. However, because they have partial protection, they survive and their life span is much longer than that of foals with CID, usually over 1 year and often 18 months. Hematologically the foal is normal unless an infection is in process, but electrophoretic examination usually reveals a marked deficiency of betaglobulins. Further tests are needed to identify the exact deficiency. A radioimmunodiffusion assay is used to quantitate serum immunoglobulins – IgA and IgM levels are usually at negligible levels, but IgG levels are discernible, although diminished. An intradermal test by injection of phytohemagglutinin determines T-lymphocyte status – a normal response is migration of mononuclear cells
- An isoimmune neonatal leukopenia can cause immune deficiency in foals; antibodies to the sire's lymphocytes are detectable in the mare's serum
- Neonatal septicemias.

TREATMENT

There is no satisfactory treatment for CID in foals. Hyperimmune serum, whole blood transfusions, and broad-spectrum antibiotics are all used without more than a temporary response. Affected foals may be kept alive by twice-weekly injections of hyperimmune serum and a constant antibiotic cover. Immunotherapy using a transplant of bone marrow and a fetal thymus transplant has been attempted without success. Corticosteroids are contraindicated.

CONTROL

Horses heterozygous for the mutation can be detected using a commercial PCR assay.[6,7] These horses have normal serum immunoglobulin concentrations and lymphocyte counts. Detection of heterozygous animals, which is required by some national breed organizations, is

useful for several reasons. Firstly, it should, ideally, permit elimination of the disease from the population by breeding of only homozygous normal animals. However, this approach has not met with success because of the financial and emotional value of some heterozygous animals. Secondly, identification of the status of an animal permits controlled breeding such that the risk of producing homozygous affected foals is eliminated. This is achieved by mating only pairs of homozygous normal animals, in which case none of the off-spring will carry the mutated gene, or by mating a heterozygous animal with a homozygous normal animal. In this instance 1 in 4 of the progeny will carry the mutated gene, but none of the progeny will be homozygous for the mutated gene and, therefore, afflicted with the disease. This second approach, if applied consistently, should almost eliminate the disease.

Specific diseases of uncertain etiology 36

INTRODUCTION 1981

DISEASES CHARACTERIZED BY SYSTEMIC INVOLVEMENT 1981
Unthriftiness in weaner sheep (weaner illthrift) 1981
Buller steer syndrome 1982
Stillbirth/perinatal weak calf syndrome 1983
Watery mouth of lambs (rattle belly, slavers) 1986
Cold cow syndrome 1987
Thin sow syndrome 1987
Acute hepatitis (postvaccinal hepatitis) of horses (Theiler's disease, serum hepatitis) 1988
Granulocytopenic disease of calves 1989
Sweating sickness (tick toxicosis) 1989

DISEASES CHARACTERIZED BY ALIMENTARY TRACT INVOLVEMENT 1990
Equine grass sickness (equine dysautonomia, grass disease, mal seco) 1990
Idiopathic chronic inflammatory bowel diseases of horses 1992
Granulomatous enteritis of horses 1992
Lymphocytic-plasmacytic enterocolitis 1993
Chronic eosinophilic gastroenteritis of horses 1993
Ovine mouth and gum obscure disease 1993
Ulceration of the *pars esophagea* of the stomach of swine (gastric ulcer, hyperkeratosis) 1994
Chronic inflammatory bowel disease of sheep 1997

DISEASES CHARACTERIZED BY RESPIRATORY TRACT INVOLVEMENT 1998
Interstitial pneumonia of cattle 1998
Tracheal stenosis of feedlot cattle 2004
Interstitial pneumonia of adult horses 2004
Acute broncho-interstitial pneumonia in foals 2005
Chronic interstitial pneumonia of foals 2005

DISEASES CHARACTERIZED BY NERVOUS SYSTEM INVOLVEMENT 2006
Polioencephalomalacia (cerebrocortical necrosis) of ruminants 2006
Equine neonatal encephalopathy (neonatal maladjustment syndrome of foals, dummy foal, barkers and wanderers) 2012
Congenital tremor syndromes of piglets 2015
Ovine humpyback 2015
Equine cervical vertebral stenotic myelopathy, (**wobbler**, 'wobbles', equine sensory ataxia, cervical vertebral instability) 2016
Stringhalt 2018
Ovine 'kangaroo gait' 2019
Equine motor neuron disease 2020
Crushed tail head syndrome in cattle 2020
Polyneuritis equi (equine cauda equina syndrome) 2021
Head shaking in horses 2022
Congenital necrotizing encephalopathy in lambs 2023

DISEASES CHARACTERIZED BY INVOLVEMENT OF THE MUSCULOSKELETAL SYSTEM 2023
Hyena disease of cattle 2023
Asymmetric hindquarter syndrome of pigs 2024
Splayleg syndrome in newborn pigs 2024
Degenerative joint disease (osteochondrosis,osteoarthrosis, epiphyseolysis, and apophysiolysis; leg weakness in pigs) 2025

Introduction

It was anticipated that, with time, this chapter would shrink in succeeding editions and, eventually, disappear. As the causes of individual diseases are demonstrated they are removed to other chapters but in the past newly identified diseases have been added at almost the same rate so that the net effect on the chapter has been small. The process could have been hastened by moving diseases when the consensus of opinion, short of proof, was that the cause had been identified. We have thought it preferable to leave those diseases here, together with those in which the combination of causes is complex, such as 'weaner illthrift'.

Synopsis

Etiology Several causes including parasitism, trace element deficiencies, pasture palatability and fungal infestations of pasture.
Epidemiology Loss of weight at weaning and failure to make satisfactory weights subsequently, in spite of the presence of ample feed and when adult sheep are faring well.
Clinical findings Poor body condition and failure to thrive.
Lesions Inanition
Diagnostic confirmation Laboratory testing for specific cause. Correction-response trial.
Treatment Correction
Control

Diseases characterized by systemic involvement

UNTHRIFTINESS IN WEANER SHEEP (WEANER ILLTHRIFT)

ETIOLOGY

A number of different diseases have been associated with this syndrome in both lambs and calves. In many cases an association has been established by a response trial but in others the association has not been established as causal. These include

intestinal parasitism, coccidiosis, infection with hemoplasma (eperythrozoonosis), deficiencies of copper, cobalt, selenium, zinc, thiamin, vitamin A, and vitamin D. A combination of these deficiencies has also been suspected.

Palatability of pasture appears a cause of illthrift in some instances, or at least associated with it, and moving the animals to a different pasture will sometimes alleviate the condition. This has been observed with perennial rye-grass (*Lolium perenne*), setaria grass (*Setaria sphacelata*), tall fescue (*Festuca arundinaceae*), and turnips (*Brassica repens*). Infestation of grass species with endophyte fungi may prove an important cause of illthrift and poor growth rates occur in calves with the 'summer syndrome' associated with the endophyte *Acremonium coenophialum* in tall fescue pastures. Infection of pasture species with toxigenic *Fusarium* spp. has been associated with ill thrift in lambs in South Africa, New Zealand, and Australia. Pasture and soil fungi have also been suspected of being associated with illthrift in sheep in eastern Canada.

EPIDEMIOLOGY

- The problem has seemed to be most severe in the **southern hemisphere** but this may be because sheep are so prevalent there
- It may also be due partly to the predominance of **Merino** and Merino-type sheep; the disease is most common in these breeds which have their own particular timorous nature which makes weaning and the need to shift for themselves more traumatic than in most other breeds
- This trait is particularly noticeable if there is **overcrowding** on pasture
- Lambs that are **weaned at light weights** are more prone to illthrift following weaning and ideally they should be 45% of mature weight when weaned
- Merino ewes have a low persistency of milk production and consequently management of the flock and the pastures is critical for effective weaning weights
- **Other management** factors likely to lead to low weaning weights and subsequent unthriftiness are multibirth lambs, small ewes, ewes with little milk, and lambs born late in the season.

Weaner illthrift does occur in breeds other than Merino and is also reported from several countries in the **northern hemisphere**. Weaner illthrift has been reported on a variety of different pastures and under a variety of different management systems.

In bad years there may be many **deaths**; in any circumstance there is a gross **delay in maturation** so that maiden lambing may be delayed to as late as 3 years of age. The economic effects can be disastrous. Illthrift syndromes are also recorded in calves although with less frequency.

CLINICAL AND NECROPSY FINDINGS

As the name indicates the disease in weaned sheep is manifest primarily by **poor body condition** and **failure to thrive**. Within an affected group not all lambs are equally affected and there will be a range of conditions. Those lambs in very poor condition are usually anemic, frequently have diarrhea, and there is a sporadic but continuing death loss amongst them. Commonly the sheep have been treated with anthelmintics with no response. There are usually no abnormal findings at postmortem other than those associated with emaciation but villous atrophy is often found on histological examination of the small intestine.

This lack of significant findings is probably the **defining factor** for placing a problem in this disease category.

DIFFERENTIAL DIAGNOSIS

When faced with this problem the initial approach should be to examine for the most likely cause which is a deficiency in energy or protein intake.

An examination of the **teeth** to insure that there is no excessive attrition of the teeth, or even breaking of the incisors if the sheep are being fed roots, is also a logical preliminary step in any investigation of an illthrift problem.

The Parasite Status of the group should be examined by techniques appropriate to their detection as outlined in previous chapters. Clinical or subclinical infestations with nematodes are common occurrences at this time in the sheep's life, before immunity is properly developed and when pasture contamination can be high.

Infections with coccidia, cryptosporidia, or *Mycoplasma* (*Eperythrozoon*) *ovis* are significant causes of illthrift and should be examined as outlined in previous chapters.

The Trace Element Status of the group should be examined if the cause cannot be found with the above examinations. Many trace element deficiencies are area deficiencies or in an area are strongly associated with certain soil types. If trace element deficiency is a cause it is likely that there will be some prior history of this problem in the area. Diagnosis by response to supplementation is a common approach and the diagnostic aspects of the trace element deficiencies are outlined under their specific headings in this text.

Examination of the above-mentioned possible causes is time-absorbing and costly and, if there is a residuum of unsolved cases, they are likely to remain undiagnosed.

Infectious Agents can produce enteric lesions and illthrift (e.g. coronavirus and yersiniosis) and the malabsorption which results may be manifested by weight loss and by chronic diarrhea. They are differentiated on the initial postmortem examinations.

BULLER STEER SYNDROME

Synopsis

Etiology Unknown. Behavioral problem of steers in feedlots
Epidemiology Prevalence varies and increases with increasing age and weight at entry.
Clinical findings and lesions Areas of denuded hair, subcutaneous hematomas, other traumatic injuries
Treatment Symtomatic
Control Removal from pen.

ETIOLOGY

The buller steer syndrome is a **behavioral** problem in cattle confined in feedlots[1] of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiogies. Improper placement of hormonal growth implants has been suspected as being associated.

EPIDEMIOLOGY

Occurrence

The syndrome occurs only in cattle in feedlots. The prevalence varies, but in one study ranged from 0 to 11% with a mean of 2.7%.[1,2] The prevalence increases with increasing weight and age.[1,2] The case fatality has been estimated at 1%.[3] The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.[4]

Epidemiological studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups.[1] The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably due to more aggressiveness in the bulls.

Risk factors

Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, daily feedlot management, weather and seasonal factors, disease, group size, and dominance behaviour. However, these factors have not been well substantiated and controlled studies have found little influence of

implant type and implant timing on buller incidence.[5]

The mixing and confinement of **unfamiliar cattle** into pen groups, with subsequent agonistic interactions as these cattle established a social hierarchy, are considered as important risk factors. Both riding behavior and antagonistic behavior cease once cattle establish a stable social hierarchy. This suggests that riding behavior and subsequent identification of bullers is associated with this dominance behavior. It is possible that when a dominant animal becomes ill in a pen, other more subordinate animals in the pen that were previously subdued in dominance contests may want to fight the sick animal to achieve higher social status

Economic importance

The syndrome has been ranked along with acute undifferentiated bovine respiratory disease and footrot as **one of the three most important disease syndromes** in beef feedlots in North America. In addition to the economic loss from decreased weight gain, injury, treatment, death, and carcase condemnation, there is economic losses associated with extra handling necessary to accommodate affected cattle, the disruption of uniform marketing of cattle, especially in custom feedlots, and the need for extra pens in which to house the bullers. The importance of the syndrome includes the animal welfare aspects.

Bullers may be at significantly greater risk of illness and mortality (from bacterial pleuropneumonia) than other steers.[2] The association between illness, mortality, and bullers among individuals was greatest among the oldest yearling steers.[2]

CLINICAL FINDINGS

Two types of bullers are identified.[3]

Type 1 or true bullers stand as if they were a heifer in estrus and do not move away or show agonistic behaviour when being mounted by rider cattlc. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged.

Type 2 bullers are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become infected and develop to subcutaneous pockets of pus and gas. Other traumatic injuries, such as limb fractures, also occur.

CONTROL

Management of the syndrome has usually involved identification and removal from the pen to prevent injury and even death from riding-related injuries.

The high rate of risk of illness and mortality in bullers relative to other feedlot steers suggests that bullers should always be checked for evidence of illness in addition to their removal from their designated pen to prevent severe riding-related injuries. Treating sick bullers may improve the chance of settling them back into their designated pen by allowing them to resume their original position in the social hierarchy.

STILLBIRTH/PERINATAL WEAK CALF SYNDROME

Synopsis

Etiology Multifactorial
Epidemiology Most commonly multiple cases on a farm. Several farms affected in a geographic region in a single season. Problem may not occur for several years and then occur as 'epidemic' in a region.
Clinical findings Calves may be born weak and unable to stand. More commonly are born apparently normal and stand but subsequently collapse with hypothermia and die within a few hours of birth.
Lesions Petechial hemorrhages, subcutaneous edema, and hemorrhage commonly in the subcutaneous tissue of the carpal and tarsal joints.
Diagnostic confirmation Specific to cause
Treatment Heat and supportive.
Control Correction of underlying nutritional defciciency.

HISTORICAL ASPECTS

A disease of newborn calves called the 'weak calf syndrome' was first recognized in Montana in 1964.[1] It has been recognized throughout the US and other countries since then, and is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth.[2] Morbidity ranged from 6 to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetrical assistance.[3]

In calves which survived for a few days, clinical findings included lassitude, depression, weakness, variable body temperature, a reddened and crusty muzzle, lameness, and reluctance to stand, enlargement of the carpal and tarsal joint capsules along with periarticular subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness but was not a major clinical finding. Treatment was ineffective and the case fatality rates ranged from 60 to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the tarsal and carpal joint regions and extending distally. Polysynovitis with hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forestomachs and abomasum also occurred. Several different pathogens were isolated from these calves but no consistent relationship between the pathogens and the lesions was ever determined.[1]

In retrospect, the **case definitions** were not well described and it is possible that several different diseases of newborn calves were lumped into the enigma of the weak calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as certain diseases of newborn calves which are characterized by such non-specific signs as lack of desire to suck, weakness, and failure to respond to therapy.

A wide spectrum of clinical and pathological findings has been associated with the weak calf syndrome. In the most common situation, which is a major diagnostic challenge, calves are born weak and die within 10–20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves which are weak after birth due to traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of the weak calf syndrome has ranged from 10 to 20% of all calves born.[4] Field observations in problem herds found that the gestation period is of normal duration but parturition is usually prolonged with the first and second stages of labor lasting 24 hours.[5] Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes often accompanied by prominent incoordinated movements of the limbs.[4] Some calves are stillborn and whether or not this is a variation of the syndrome is uncertain. In a report from the UK, the syndrome occurred in calves born from heifers and was characterized

by failure to breathe at birth, or breathing with difficulty, and/or failing to move after birth, and failure to suck.[6] The term stillbirth/perinatal weak calf syndrome has been suggested as more appropriate.

Dummy calf syndrome

A variation of the weak calf syndrome is the dummy calf syndrome reported from the southern US.[7] Affected calves appear normal at birth, are generally alert, but lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected calves did not stand for up to 1–2 hours after birth to initiate teat-seeking.[7] Dummy calves appear to lack the sensitivity to teat-seek and if they fail to locate a teat by about 4–5 hours after birth they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves which fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it. The cause is unknown but is thought to be a behavioral disorder inherent in some breeds; this has not been supported with any scientific evidence.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of the weak calf syndrome is unclear, but several epidemiological observations have suggested some possible causes.[8] These include:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetrical assistance
- Fetal hypoxia from prolonged parturition.

Fetal infections

Fetal infections in the last few days before term can result in stillbirth or weak calves which may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, leptospiral infection was present in 25% of them.[8] Calves in which leptospiral antigen was detected in the placenta were significantly lighter by an average of 6 to 10 kg than calves with no antigen in the placenta.[9] Calves infected with *Leptospira* in the uterus were more likely to be infected by *Arcanobacterium pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower bodyweight. The adrenal gland, lung, and placenta are most useful tissues to examine for leptospiral antigen.[9]

There is some evidence that an immune inadequacy based on T lymphocyte function may be associated with the weak calf syndrome in Japanese Black calves but the data are not compelling.[10]

An unidentified type of adenovirus has been associated with the weak calf syndrome on a large dairy farm in Israel.[11] At birth the calves were reluctant to suck or drink colostrum and were force fed colostrum with a gastric tube. Affected calves were weak at birth, unable to rise without assistance and when forced to move, walked stiffly, suggestive of polyarthritis. An adenovirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

Maternal nutritional deficiency causing fetal underdevelopment

Hypothyroidism due to iodine deficiency in the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves.[12] Analysis of the laboratory data from 365 calves which died from the stillbirth/perinatal weak calf syndrome in Ireland, found some differences between calves with an abnormal and normal thyroid gland.[13] Glands weighing more than 30 g were probably abnormal. Abnormal glands were heavier, consititued a greater percentage of the calfs bodyweight and had a lower iodine concentration. A higher proportion of calves with an abnormal thyroid gland had uninflated lungs and pneumonia. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine deficient diet over the last 4 to 5 months of pregnancy resulted in clinicopathological changes and pathological changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine deficient group were born clinically normal.[8]

A **maternal dietary deficiency of selenium** in pregnant cattle has also been examined but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium.[4,5] The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds where the incidences were 7.9% and 7.4%, respectively.[14] A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller than normal calves but the deficiency usually must be grossly inadequate. Radiographic examination of affected calves found that intrauterine growth retardation is not a common feature in calves dying with the syndrome.[15]

Placental insufficiency

Intrauterine growth retardation associated with feto-placental dysfunction has been described in Japanese Black beef calves.[16] Affected calves were weak when born at term and were underweight compared to normal calves. Anemia due to bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Dams delivering weak calves had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves suggesting a feto-placental dysfunction. The dysfunction was influenced by sires and maternal families.

Fetal hypoxemia

Fetal hypoxemia due to a prolonged parturition or dystocia may be a cause of the weak calf syndrome.[17] While asphyxia is not an integral part of normal delivery, it is still an important cause of fetal death during abnormal parturitions. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which results in death during delivery or shortly after.[18]

In newborn mammals subjected to anoxia, initially there is a period of struggling and rapid gasping during which blood pressure rises and bradycardia becomes profound. A relatively short period of primary apnea follows, after which there is a period of more regular and deeper gasping, which may become more frequent terminally. This is followed by a period of secondary apnea, the heart rate continues to beat at a slowly declining rate, and blood pressure falls slowly. The brain lesions begin in lower brainstem nuclei and, as asphyxia becomes prolonged, progress to involve the cerebellar and thalamic nuclei and the cerebral cortex. Examination of blood gas values on newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction may result in a severe acidosis due to oxygen deprivation. As blood pH drops, first vitality is reduced, subsequently vital organs like the brain are damaged and ultimately the fetus dies.[19]

The bovine fetus appears relatively susceptible to anoxia which has been studied experimentally by clamping the umbilical cords of fetuses for 4–8 minutes, at 24–48 hours before expected birth, followed by a cesarean section 30–40 minutes later. Calves born following this procedure may die in 10–15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes

but most will die following 6 or 8 minutes of anoxia.[17] During the clamping of the umbilical cord, there is a decline in the blood pH, PO_2 and standard bicarbonate levels and an increase in the PCO_2 and lactate levels.[17] Hypoxia in neonatal calves can result in high plasma lactate concentrations, which contributes to a progressive primary metabolic acidosis.[20]

During the clamping there is also increased fetal movement and a release of meconium which stains the calf and the amniotic fluid. Those which survive for a few hours or days are dull, depressed, cannot stand, have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy.

Some calves whose umbilical cords were clamped for 4 minutes were born weak, and made repeated efforts to raise their heads and move onto their sternum but were unable to maintain an upright position for long. These calves become hypothermic, dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and commonly develop diarrhea and other complications.

Dystocia and traumatic injuries at birth

Dystocia is a major cause of neonatal mortality in range beef cattle and may be a cause of the weak calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetrical assistance.[21,22] In a study of 13 296 calvings over a period of 15 years in two research herds in Montana, calf mortality due to dystocia accounted for the single largest loss category through the first 96 hours postpartum.[21] Dystocia accounted for 51% of calf deaths and 53% of dystocia deaths occurred in calves which were born without assistance. Calf deaths from primiparous 2- and 3-year-old dams accounted for 41% of total mortality. Necropsies done on 798 of 893 calves found that 77.7% were anatomically normal and 22.3% abnormal. At necropsy of the calves which died associated with dystocia the findings included a froth-filled trachea, non-functional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetrical assistance at the right time could have reduced the mortality associated with dystocia.

Similar reports of weakness following dystocia have been reported; in some cases a collapsed trachea is present.[23] In a study of parturient calf mortality in Australia, death rates as high as 44% from heifer groups have been reported.[24] The death rate was significantly higher in male calves than female calves. Pathological changes in many of the dystocia-related deaths were minimal but a congested swollen tongue was a definitive lesion.

Traumatic injuries of calves at birth are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate.[25] Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves which died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathological evidence of asphyxia. Calves delivered by extraction had pathological evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs[26] and represent evidence of perinatal respiratory distress.[27] The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.[28]

Premature expulsion of placenta

Premature expulsion of the placenta has been associated with perinatal calf mortality.[29] Field observations indicate that the majority of affected fetuses die from fetal hypoxia during stage two of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposture. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf.[30] In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.[29]

NECROPSY FINDINGS

All calves which die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves.

In the weak calf syndrome described in Northern Ireland, at necropsy, many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium and the parietal pleura and endocardium.[8] These lesions were similar to those present in animals which died of acute terminal asphyxiation.[18] The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intrapartum stillbirth in piglets and contributes to early postnatal mortality.[18] Froth may be present in the caudal trachea of some calves which die within 10–20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intra-abdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage.[6] Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints due to the pressure applied by the obstetrical chains or ropes.

In the syndrome described in the US, the lesions either appeared at birth or developed in the first few weeks of life.[1] At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints and extending distally down the limbs. The synovial fluid may be blood-tinged and contain fibrinous deposits. Erosions or ulceration of the gastrointestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

Samples for confirmation of diagnosis

- Bacteriology – fetal liver, lung, stomach content, adrenal gland; placenta (CULT). Special detection techniques for Leptospira antigens.
- Histology – fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (LM, IHC)

DIFFERENTIAL DIAGNOSIS

Determination of the cause of the weak calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than about 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

Case definition

When an epidemic of the disease is encountered, an epidemiological investigation of the herd is necessary in an attempt to identify possible risk factors.

The patterns of occurrence should be determined:

- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows with a consequent greater incidence of weak calves born from the cows
- Is there any evidence that parturition is prolonged in the heifers or the cows and what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetrical assistance is provided?
- Is it possible that some nutritional, management or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves and what are the relative birth weights?
- How soon after birth are the calves affected?
- What is the course of the illness after the first clinical abnormalities are noted?
- What level of calving surveillance and assistance is being provided by the attendants?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

TREATMENT

Calves born weak, unable to stand, lacking the instinct to seek the teat or lacking a suck reflex, need intensive care including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications. Affected calves must be assisted to suck the dam normally. Bottle feeding for a few days may be necessary until the calf becomes strong enough to suck the dam on its own.

CONTROL AND PREVENTION

Control and prevention of the weak calf syndrome is based on empirical observations beginning with insuring **adequate nutrition of the dam** to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of **adequate surveillance at calving time** and competent obstetrical assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetrical assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition and observe the parturition process and the health of the calves at birth.

WATERY MOUTH OF LAMBS (RATTLE BELLY, SLAVERS)

Synopsis

Etiology Non-enteropathogenic *E. coli* endotoxemia predisposed by failure of passive transfer
Epidemiology Higher risk with intensive housing with poor hygiene
Clinical findings Loss of sucking reflex, retention of meconium or feces, excessive mucoid saliva, abomasal distension.
Lesions None specific
Diagnostic confirmation Nothing pathognomonic.
Treatment Fluids and energy via stomach tube. Antimicrobials.
Control Antimicrobials at birth, pen hygiene, ensure adequate colostral transfer

ETIOLOGY

This disease is believed to be the result of **endotoxemia** in young lambs. It is postulated that the neutral pH of the abomasum in newborn lambs, coupled with low concentrations of colostral immunoglobulin in the gut, allow rapid multiplication of non-enteropathogenic strains of *Escherichia coli* in the gut, and to some extent systemically, to result in endotoxemia.[1]

EPIDEMIOLOGY

Occurrence

The syndrome is primarily reported in **lambs** in **Great Britain** but has also been reported in New Zealand and in goat kids in Spain and North America.[1,2]

Animal and environmental risk factors

Lambs 12 to 72 hours of age are affected. The disease is seen under all management systems but is rare in pastured flocks and occurs most commonly in lambs kept in **intensive housing** where there is **poor hygiene** of the lambing environment. Lambs from prolific ewes are at risk and the disease is more common in triplets than twins or singles.

Delayed or **poor colostral intake** is a major risk factor and situations that predispose this may lead to outbreaks. A high prevalence has occurred in ram lambs castrated by the use of an elastic band at a very young age and the resulting pain may have dissuaded them from feeding.

Other risk factors, all of which reduce sucking by the lamb, are inclement weather, mismothering, maternal agalactia, competition between twins or triplets, low vitality, and ewes in poor condition.

Experimental reproduction

An equivalent clinical syndrome is reproducible by administering non-enterotoxic strains of *E. coli* by mouth to colostrum-deprived lambs, all of whom died within 24 hours.[3]

Economic importance

Watery mouth disease is a major cause of mortality of housed newborn lambs in Great Britain and is reported to be the cause of approximately 25% of all deaths of lambs in indoor intensive lambing systems.[1] Where conditions allow morbidity rates may approach 24% and without early treatment case fatality rates are high.[4]

PATHOGENESIS

Gram-negative bacteria, non-enterotoxigenic and non-enteropathogenic *E. coli* in the environment, are ingested as a result of a contaminated environment, or from a contaminated fleece, and survive passage through the neutral pH of the abomasums to be absorbed into the systemic circulation by the natural pinocytosis that occurs in the intestinal epithelium of newborn ruminants, to produce an endotoxemia.

CLINICAL FINDINGS
Affected lambs are normal at birth but become sick at 24–48 hours and up to 72 hours old. The disease is characterized by dullness, a complete failure to suck, and excessive mucoid saliva around and drooling from the mouth. As the disease progresses there is hypothermia, failure to pass feces, cold extremities, depression to the point of coma, anorexia and, in the late stages, abdominal distension and recumbency, but rarely diarrhea. The alimentary tract is full of fluid and the lamb rattles when it is shaken. Some lambs are hypothermic but the temperature is normal at the onset of the condition and falls to subnormal as the disease progresses. Progress is rapid with death 6–24 hours after the first signs of illness.

CLINICAL PATHOLOGY
Total protein concentrations and base excess values are significantly elevated compared to normal lambs.[5] Blood glucose concentrations are normal but may be low in the terminal phase of the disease.

NECROPSY FINDINGS
There are no findings specific to the syndrome. The abomasal contents are fluid and mucoid, and contain small milk curds and the intestine is gas filled.

TREATMENT
Treatment with intramuscular amoxycillin and clavulanic acid, intravenous flunixin meglumine, and oral rehydration fluid, when administered early in the clinical course, has resulted in a high recovery rate in field cases.[5] Dextrose solution should also be given to those lambs that are hypoglycaemic and external warming should be provided. Other recommended treatments include emptying the alimentary tract by purgation or enema.

DIFFERENTIAL DIAGNOSIS
Most neonatal disease of lambs is manifest with diarrhea which is not present in watery mouth. The early stages of Colisepticemia and Clostridium perfringens type B or C present with similar clinical signs but are easily differentiated later in the clinical course or at post mortem examination. Hypothermia/starvation/cold stress can present with similar clinical findings but the history and environmental circumstances of occurrence differ.

CONTROL
In outbreaks the administration of antibiotics to all newborn lambs within 15 minutes to 2 hours of birth dramatically reduces the occurrence of further cases.[4–6] Fresh or frozen sheep or cow colostrum should be supplemented to lambs at risk. The provision of ewe colostrum at 50 mL/kg body weight within 6 hours of birth prevents the disease.

Lambing areas and associated pens and yards should be kept clean and fresh bedded. Contaminated fleece should be removed from around the udder of the ewe prior to lambing and every effort should be made to insure early and adequate colostral intake by newborn lambs, especially for twins and triplets.

COLD COW SYNDROME
This is a herd disease problem reported from the UK in cows freshly turned out onto lush pasture with a high (27–43%) soluble carbohydrate content.[1] There is a high morbidity (up to 80%) and a large number of outbreaks in an area. The syndrome includes hypothermia, dullness, inappetence, agalactia, and profuse diarrhea. Affected cows feel cold to the touch. Some have perineal edema, some collapse. The herd milk yield falls disastrously but there is a quick return to normal if the cows are moved to a different field. The problem may occur on the same pasture each year and recur if the cows are returned to the same pasture. There is no obvious clinicopathological abnormality. It is postulaed that the syndrome might be due to zearalenone or related metabolites produced by field micro fungi in the pasture.[2]

THIN SOW SYNDROME

Synopsis

Etiology The syndrome is the result of inadequate nutrition and unbalanced nutrition in pregnancy and lactation but can also result from parasitic or chronic infectious disease.
Epidemiology Loss of weight to the point of inanition particularly in first and second litter gilts.
Clinical findings Inanition
Control Recognition of the relation between voluntary feed intake in pregnancy and lactation, feeding based on condition scores.

ETIOLOGY
The 'thin sow syndrome' is discussed in this chapter because of its multiple etiology. Regardless of etiology the effects of this syndrome on fertility and overall farm productivity can be formidable. There are a number of causes of wasting and the occurrence of thin sows:

- The major cause of sow abnormality under this heading results from **errors in feeding** and management, which are likely to be exaggerated and multiplied on farms where intensive management is practiced. The most common errors are incorrect feeding in pregnancy and lactation. These can be exacerbated by cold or drafty housing, fluctuating temperatures, too high a temperature in the farrowing house, low-level feeding to avoid obesity, wet bedding, and lack of drinking water. Early weaning increases the risk for the thin sow syndrome, especially if nutrition is inadequate.
- **Parasitic disease**, particularly associated with infestation with *Oesophagostomum* spp. and *Hyostrongylus* spp. Is a cause of wasting in sows and the occurrence of the thin sow syndrome and is discussed under those headings (Ch. 27)
- Thin sows can be a component of the syndrome of **infectious diseases** such as cystitis and pyelonephritis .

EPIDEMIOLOGY AND PATHOGENESIS.
The syndrome is most common in first and second litter gilts but can affect all parities when nutrition is inadequate. It emerged as a problem in the 1970s as a result of poor understanding of the **inter-relation between feed intake in pregnancy and that in lactation**, combined with the move to intensive indoor housing of pregnant sows. Penning of sows exacerbated social dominance/submissive relationships. The voluntary intake of food by sows during lactation is inversely related to the intake in pregnancy. Consequently sows that are fed at high levels during pregnancy will gain excessive weight during pregnancy but will voluntarily restrict feed intake during lactation and loose excessive weight during lactation. In contrast sows that are fed what is basically a maintenance ration 2.0–2.5 kg (4.5–5.5 lbs) of a balanced sow ration during pregnancy will gain adequate weight for conceptus and body growth and during lactation will consume adequate feed for lactation requirements and loose minimal weight in this period. Knowledge of sow nutrition has improved such that major problems with this syndrome should not occur but there is still a risk of

inadequately feeding sows selected for lean genotype and high litter size and weaning weights. First and second litter gilts may require more feed to provide for body growth.

CLINICAL FINDINGS

Within a herd the thin sow syndrome develops over a period of months and often one or two pregnancy cycles, with a gradually declining of body condition of the group until 20% to 30% of sows have a low body condition score. No abnormalities are evident on clinical examination but the sow fails to regain weight after weaning, particularly sows after their first litter. The most critical period for weight loss is the first 2 weeks after weaning. Affected sows have a poor appetite but often show pica and excessive water intake and may be anemic.

CONTROL

Feeding during pregnancy

Currently the risk for the thin sow syndrome exists where it is assumed that all pregnant sows can be fed a standard amount of ration. Problems are likely to occur when sows are run in groups and fed as a group where timid sows are likely to be bullied out of their required share of food.

Individual feeders or stall feeding will prevent this.

Feeding during lactation

The critical issue is to ensure adequate feed and energy intake during lactation. This can be achieved by:

- not feeding to excess during pregnancy
- restricting the feed intake of sows in the first few days after farrowing to encourage better feed intake in later lactation
- ensuring an adequate and constant supply of water
- ad lib feeding during lactation
- a high-energy-density lactation diet
- enclosing the creep with heat for the piglets so that the farrowing house can be kept at a lower temperature 65°F (65°C) for the sow
- control of parasitic disease.

Condition scoring is a valuable guide to the feeding of individual sows and for a judgement of feeding practices in the herd as a whole. On a score of 1 to 5 it should be very rare to find sows with condition scores of 1 or 5. The optimum is to have sows entering the farrowing house between condition score 3 and 4 and not less than 2.5 at weaning. First and second parity sows in poor condition at weaning are best 'skipped' at the first heat and mated on the second heat.

Methods for condition scoring and guidelines can be found at http://www.defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigsctoc.htm

ACUTE HEPATITIS (POSTVACCINAL HEPATITIS) OF HORSES (THEILER'S DISEASE, SERUM HEPATITIS)

An acute hepatopathy of horses often associated with administration of equine biological products such as tetanus antitoxin.

ETIOLOGY

Etiology is unknown, although an infectious agent is suspected.

EPIDEMIOLOGY

The disease occurs in horses administered equine serum or tissue products. The first reports of the disease were in horses in South Africa administered equine serum as prophylaxis for Africa Horse Sickness. Outbreaks of the disease have occurred in horses in Africa, Europe, and North America administered equine serum as prophylaxis for a variety of diseases including African horse sickness, encephalomyelitis, botulism, *Strep. equi* infection, tetanus, and influenza and in mares given pregnant mare serum.[1] Most sporadic cases of the disease appear to be associated with administration of tetanus antitoxin.

The disease is reported only from adult horses (>1 year of age) and most cases are reported in the summer and autumn.[2] There is a suspicion that pregnant mares are at increased risk.

The **morbidity rate** in outbreaks among horses administered equine serum ranges between 2 and 18%,[3] although the rate among horses administered tetanus antitoxin as prophylaxis following injuries is clearly much lower. Acute hepatitis developed in 4 (0.4%) of 1260 horses >1 year of age administered commercial equine plasma at one institution in the United States over a 6-year period.[4] The disease can occur after intrauterine infusion of equine serum to mares.

The **case fatality** rate is between 50 and 90%.

The disease occurs sporadically in horses that have not been administered equine biological products. There are reports of in-contact, non-treated horses developing the disease.

PATHOGENESIS

Destruction of hepatocytes results in hepatic dysfunction. Hepatoencephalopathy develops in severely affected horses.

CLINICAL FINDINGS

The disease usually occurs after an **incubation period** of 40–70 days (range 27–165 days). Depression, anorexia, and icterus are evident in mildly affected cases. There may be mild to moderate colic. Body temperature and heart rate are usually normal. Acutely affected, or horses observed infrequently, can die unexpectedly. Signs of **hepatoencephalopathy** include restlessness, excitement, compulsive walking and head pressing, abnormal head position, seizures, apparent blindness, muscle tremors, and ataxia. Affected horses often injure themselves by walking into fences and troughs.

CLINICAL PATHOLOGY

Leukocytosis with neutrophilia and mild lymphocytopenia is common. The hematocrit and plasma total protein concentrations may be mildly increased. Hyperbilirubinemia and an increase in direct (conjugated) bilirubin concentration are present and serum bile acid concentration is increased, as is serum activity of liver specific enzymes aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), and sorbitol dehydrogenase (SDH). Increases in serum GGT activity is often less than expected for the increases in serum AST, SDH, and bile acid concentrations, likely reflecting the primary insult to hepatocytes.

Hypoglycemia (<2 mmol/L, 40 mg/dL) and hyperammonemia (>150 μmol/L) may be severe. Clotting time, especially the one stage prothrombin time, may be prolonged.

NECROPSY FINDINGS

The liver may be enlarged, normal or shrunken and discolored slightly yellow to green. There is severe centrilobular necrosis of hepatocytes with mild infiltration of lymphocytes and plasma cells. Alzheimer type II astrocytes are present in the brains of horses with encephalopathy.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation antemortem is achieved by examination of a liver biopsy, although this should not be performed in animals with coagulation abnormalities.

Differential diagnosis list:

- Acute aflatoxicosis
- Rubratoxicosis (Penicillin rubrum)
- Pyrrolizidine alkaloid intoxication
- Dioxin intoxication
- Idiopathic hyperammonemia.[5]

TREATMENT

Treatment is essentially supportive and consists of correction of metabolic and acid–base abnormalities, reduction of plasma ammonia concentration, and preventing horses with hepatoencephalopathy from injuring themselves.

Hypoglycemia and dehydration can be corrected by intravenous administration of

5% dextrose and isotonic electrolyte solutions. Metabolic acidosis can be corrected by infusion of sodium bicarbonate. Plasma transfusions may be necessary to correct coagulation abnormalities.

Hyperammonemia can be treated by giving neomycin (20 mg/kg, orally, every 6 hours for 4 doses) or lactulose (0.25 mL/kg, orally every 8 hours) to decrease absorption of ammonia from the gastrointestinal tract.

Sedation with xylazine or similar compounds may be necessary to prevent the animal injuring itself. The affected horse should be housed in an area where it has the least opportunity to injure itself, and may need to be fitted with a padded helmet.

CONTROL

Minimal use of biologics, including plasma, of equine origin is prudent.

GRANULOCYTOPENIC DISEASE OF CALVES

A fairly widespread disease of recent origin, granulocytopenic disease of calves is commonly ascribed to poisoning with furazolidone. Affected calves are those being reared on milk replacer and sometimes, but not always, receiving prophylactic antibiotics.[1,2]

Affected calves show persistent fever, and increased salivation and nasal discharge, and there are hemorrhages and necrotic lesions in the mouth and lower alimentary tract. The disease is characterized by decreased myelopoiesis in bone marrow, neutropenia, and thrombocytopenia. The course varies from 2 to 5 days, and the mortality rate is high, apparently from bacterial invasion. Pneumonia, peritonitis, and enteritis are common accompaniments. *Fusobacterium necrophorum* can be isolated from necrotic lesions.[1] These clinical, pathological, and hematological findings resemble those of radiation sickness, and poisoning by bracken fern.

The disease has been related to long-term feeding of furazolidone (2 mg/kg BW daily), either in the milk replacer or as specific therapy, and the disease can be reproduced by this means. At higher dose rates (20–30 mg/kg BW) nervous signs, including convulsions, and death follow within a few days; both syndromes may occur at the same time in a group of calves.[3]

SWEATING SICKNESS (TICK TOXICOSIS)

Synopsis

Etiology Unknown, associated with bites of *Hyalomma truncatum*.
Epidemiology Reported in Africa, India, and Sri Lanka affecting calves 2 to 6 months of age.
Clinical findings Fever, salivation, lacrimation, hyperemia of mucosae, epistaxis, and extensive and severe dermatitis, necrosis of oral epithelium
Lesions Dermatitis and necrotic stomatitis, disseminated intravascular coagulopathy.
Treatment Symptomatic and use of hyperimmune serum
Control Tick control

ETIOLOGY

The cause has not been identified, but it behaves as though it were an epitheliotropic toxin produced by the salivary glands of certain strains of the tick *Hyalomma truncatum*. Not all strains of *H. truncatum* have the ability to produce the disease and antigens unique to sweating sickness-inducing strains are described.[1,2]

EPIDEMIOLOGY

Attempts to transmit the disease between animals by mediate or immediate contact and by injections of tissue or blood are unsuccessful. The disease occurs in Central, East and South Africa, Sri Lanka, and probably southern India. Only calves 2–6 months of age are affected as a rule but rare cases occur in adults. Sheep, pigs, and goats are susceptible, although the disease does not naturally occur in them, and the disease has been produced experimentally in dogs. Sweating sickness occurs at all times of the year but is most prevalent during the wet season when ticks are more plentiful. The morbidity rate varies with the size of the tick population but is usually 10–30%. The case fatality rate is up to 30%.

PATHOGENESIS

The clinical signs begin 4–7 days after the ticks attach, probably 3 days in experimental infestations. The effects are dose-specific; if the ticks are removed very early there is no clinical response and the animal remains susceptible; with a longer exposure before the ticks are removed the animal becomes immune but shows no clinical signs. With longer exposure of more than 5 days the subject develops the full-blown clinical disease and may die. If it recovers it has a solid and durable immunity.

CLINICAL FINDINGS

There is a sudden onset of fever up to 41°C (106°F), anorexia, hyperemia of the mucosae, and hyperesthesia. The animal is lethargic, depressed, dehydrated, and has a serous then mucopurulent oculonasal discharge, an arched back, and a rough coat. There is an extensive, moist dermatitis commencing in the axilla, groin, perineum, and at the base of the ears which extends to cover the entire body in bad cases. 'Sweating' refers to this moist dermatitis. The hair is matted together by exudate and moisture collects in the form of beads on the surface. The eyelids may be stuck together. Subsequently patches of the skin and hair are rubbed off or can be pulled off to leave raw, red areas of subcutaneous tissue exposed. The tips of the ears and tail may slough.

Affected calves seek shade and their skin is very sensitive to touch. Later it becomes dry and hard, and cracks develop. Secondary bacterial infection and infestation with blowflies or screw-worm larvae are common sequelae. The oral mucosa is hyperemic at first and then becomes necrotic with the formation of ulcers and diphtheritic membranes. The calf salivates profusely, cannot eat or drink, and becomes emaciated and rapidly dehydrated. There are similar mucosal lesions in the vagina and nasal cavities, the latter causing dyspnea. The severity of the mucosal lesions appears to vary with different 'strains' of the toxin.[3] There may be abdominal pain and diarrhea in some calves.

The course may be as short as 2 days but is usually 4 or 5 days. In recovered animals the skin may heal and the hair may regrow, but there may be permanent, patchy alopecia and the calves may remain stunted and unthrifty.

CLINICAL PATHOLOGY

There is a severe neutropenia and eosinopenia and a degenerative left shift. α-globulin and beta-globulin levels are raised. Urinalysis indicates the existence of nephrosis but serum creatinine levels are normal.[4] Dermatological examination fails to reveal the presence of any of the usual infectious causes of dermatitis.

NECROPSY FINDINGS

The lesions are essentially those seen clinically. There is also evidence of severe toxemia, dehydration, emaciation, and hyperemia of all internal organs and disseminated intravascular coagulation. The necrosis of the oral epithelium extends into the esophagus and may reach the forestomachs.

DIFFERENTIAL DIAGNOSIS

The combination of extensive dermatitis and mucosal necrosis is unusual. Mucosal disease and bovine malignant catarrh may bear some resemblance and there could be difficulty in differentiation in areas where the tick *Hyalomma truncatum* occurs.

TREATMENT

There is no specific treatment; efforts should be directed at relieving the severity of the dermatitis and mucosal loss. Non-steroidal anti-inflammatory drugs (NSAIDs) and broad-spectrum antibiotic cover is a logical regimen. Hyperimmune serum, produced in sheep and cattle by infesting them with *Hyalomma truncatum* at 6-week intervals for 2–5 occasions, is an effective treatment in pigs, sheep, and to a less extent calves.[2,5]

CONTROL

Control is limited to control of the causative tick. No vaccine is available.

Diseases characterized by alimentary tract involvement

EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA, GRASS DISEASE, MAL SECO)

Synopsis

Etiology Unknown
Epidemiology Horses of all breeds and both sexes in the UK, Western Europe, Scandinavia, and southern South America. Greatest incidence in early summer.
Clinical signs
Acute grass sickness: Colic, nasogastric reflux, absent gut sounds, depression, dysphagia, and small intestinal distension of <2 days duration at time of death.
Subacute grass sickness: Tachycardia with or without signs of colic, reduced intestinal sounds, impaction of the colon, and clinical course of 2–7 days.
Chronic grass sickness: Insidious onset weight loss, intermittent colic, decreased appetite, rhinitis sicca, patchy sweating, and mild dysphagia.
Clinical pathology None is specific or diagnostic.
Lesions Both forms of the disease have degeneration of neurons of the autonomic nervous system, especially of the myenteric and submucosal plexuses.
Diagnostic confirmation Examination of ileal biopsy.
Treatment
Acute grass sickness/subacute grass sickness: Supportive. None effective.
Chronic grass sickness: Nursing care. Cisapride.
Control None

ETIOLOGY

The cause is unknown but is suspected to be a neurotoxin, possibly *Clostridium botulinum* toxin, based on epidemiologic data.[1,2] Evidence supporting a role for *Cl. botulinum* in the etiology of the disease included the isolation of toxin (BoNT/c) producing strains of *Cl. botulinum* type C from the ileum of 45% of horses with grass sickness and 4% of clinically normal control horses.[2] In addition to preventing the release of acetylcholine at cholinergic nerve terminals and thereby causing paralysis, a function that it shares with other botulinum toxins, BoNT/C is neurotoxic. Other studies have demonstrated increased numbers of bacterial organisms, including anaerobes, and number of species of clostridia in feces of horses with grass sickness compared with normal horses.[3] Whether these findings represent a causative role of *Cl. botulinum* in grass sickness, or an effect of the modified gastrointestinal motility and on intestinal flora remains to be determined. Further evidence to support a role for *Cl. botulinum* in the etiology of grass sickness include the observations that low serum concentrations of antibodies to *Cl. botulinum* are associated with increased risk of the disease.[1,4] However, the hypothesis of a role for toxicoinfectious botulism in grass sickness of horses does not explain the geographic distribution of the disease given that botulism occurs worldwide in horses and grass sickness does not.

EPIDEMIOLOGY

Occurrence

Grass sickness is not common and appears to be restricted in its distribution to all parts of Great Britain (including possibly Ireland), Sweden, and the northern and western coasts of Europe. A clinically and histologically indistinguishable disease, *mal seco* occurs in the Patagonia region of Argentine, southern Chile, and in the Falkland (Malvinas) Islands.[5,6]

Horses, ponies, donkeys, zebra, Prrzewalski's horses, rabbits, and hares are the predominant species affected.[7] The morbidity and mortality rates are not reported, but the **incidence** on farms with a history of the disease ranges between 0.4 and 16% per year[8] or 2.1 grass sickness cases per 100 horses per year.[9]

The **case fatality rate** for acute grass sickness is 100%, while that for the chronic form of the disease in horses treated at a referral hospital is 60–70%.[10,11] Horses that survive the chronic form of the disease are often destroyed because of weakness and emaciation, although make complete recoveries.[12] However, given the difficulty in establishing an antemortem diagnosis, it is unclear whether horses that fully recovered actually had chronic grass sickness.

Risk factors

Animal risk factors

The risk of disease is greatest in 4–5 year old horses (adjusted odds ratio of 1.9 compared with 0–3 year olds) and then declines such that the risk of disease is lowest in horses >12 years old (odds ratio 0.02 compared to that of 0–3 year olds).[1] Cases in horses 10 months to 20 years of age have been encountered. Foals born of affected mares are clinically normal.[13] There is no apparent breed predilection.[8]

Horses at pasture are at increased risk (hence the colloquial name of the disease), although the disease does occur rarely in stabled horses. A recent (<14 day) change of pasture carries an increased risk (odds ratio 24) of development of the disease.[14] Horses that have been on the farm for less than 2 months are at increased risk of developing the disease.[8] Horses on farms with previous cases of the disease are at increased risk (odds ratio 2.2–45) of the disease,[14,15] although horses that have been in contact with animals with the disease are at reduced risk (odds ratio 0.1) of developing the disease.[14]

Environmental risk factors

There is a marked seasonal distribution of cases, with the peak incidence occurring in early summer in the British Isles.[8,9,16] Outbreaks of the disease are associated with the occurrence of cooler and drier weather than normal during the 2 weeks preceding the outbreak,[9,17] although this is not consistently reported.[15]

Farm or premise risk factors

As mentioned, farms with a history of horses with the disease are at increased risk of having further cases. For premises with previous cases of grass sickness there is an increased risk of the disease developing as the number of horses on the farm increases, with the presence of young horses, on stud farms and livery/riding schools, on farms having sandy or loamy

soil, and those rearing of domestic birds and using mechanical fecal removal.[9] The risk of recurrence of disease on a farm decreased with presence of chalk soil, cograzing ruminants, grass cutting of pastures, and manual removal of feces.[9] There is no association between the disease and the type of pasture, nor with provision of supplementary feeds.[8] Feeding hay or haylage is associated with a decreased risk of the disease.[1] Any disturbance of the soil, such as by ploughing, increases the risk of disease.

Transmission

The disease is not contagious. Injection of normal horses with serum of affected horses causes lesions, but not clinical signs, consistent with the disease.

PATHOGENESIS

The clinical signs are attributable to widespread damage to the autonomic nervous system, resulting in sympathetic and parasympathetic dysautonomia that is most clinically evident in the gastrointestinal tract. Coincident with damage to the autonomic nervous system are increases in plasma concentrations of dihydroxyphenylalanine, epinephrine, norepinephrine, and dopamine,[18] possibly because of increased secretion of these compounds from affected sympathetic ganglia and neurons.[19] Lesions in the cranial nerves and brain stem are probably responsible for dysphagia and drooling evident in most cases. Rhinitis is associated with diminished nonadrenergic, noncholinergic (NANC) innervation, greatest in neurons positive for substance P or calcitonin gene-related peptide, of the nasal mucosa in subacute and chronic cases.[20]

Electrocardiographic examination of affected horses reveals evidence of loss of parasympathetic innervation of the heart, which is consistent with lesions in the terminal cardiac ganglia.[21] Splanchnic lesions are most severe in the myenteric and submucosal plexuses of the ileum, with less severe changes in the large colon and celiaco-mesenteric ganglion.[22] There is also a reduction in interstitial cells of Cajal (cells involved in pacemaker activity and autonomic transmission within the gut).[23] These neuronal changes are associated with a marked impairment of cholinergic activity in ileal tissue of affected horses.[24] Because of the altered autonomic activity, peristalsis decreases (in chronic cases) or ceases (in acute cases) with subsequent accumulation of ingesta in the small intestine, stomach, and large colon. Death is due to emaciation in chronic cases or rupture of the stomach or intestine in acute cases.

CLINICAL FINDINGS

The clinical signs of grass sickness are varied, and accurate diagnosis on clinical signs alone is very difficult. The incubation period of the disease is approximately 10–14 days[17]. **Acute, subacute, and chronic** forms of the disease are recognized,[25] although some authorities use a designation of acute and chronic.[26] In all cases, there is some dysphagia, resulting in drooling of saliva and trickling of ingesta from the nose. Dried food is impacted between the cheeks and the teeth and the animal plays at drinking. These signs are attributable to lesions in the cranial nerves. Most animals are depressed.

Acute cases the onset is sudden and the course of the disease is 1–4 days. Abdominal pain may be severe but also may be absent even in the presence of severe tachycardia. There is tachycardia (80–90/min may be >100), decreased to absent gut sounds, lack of defecation, and abdominal distension. On rectal examination, there are hard, dry pellets of feces, the large colon contains firm ingesta which has a corrugated feel that is quite distinct to the smooth surface of a primary colonic impaction. The small intestine is distended with fluid and readily palpable in the caudal abdomen. Nasogastric intubation yields a large (20 L) quantity of fluid. Urination is frequent and may be accompanied by tenesmus. Affected horses may wander about in a restless manner and a fine muscle tremor occurs constantly, especially in the upper forelimb. Periodic attacks of patchy sweating occur commonly. There is noticeable salivation. Esophageal endoscopy reveals linear ulcerations resulting from reflux esophagitis.

Subacute cases have signs of mild colic, or may not have any signs of colic, in the presence of tachycardia, depression, reduced gastrointestinal sounds, and impaction of the large colon with characteristic corrugated appearance.[25] The clinical course is 2 to 7 days and death is inevitable. Esophageal endoscopy reveals the presence of linear erosions in many affected horses.

Chronic cases the course is usually >7 days and is characterized by weight loss, patchy sweating, and intermittent colic. Horses stand with all four feet close together under them ('elephant on a tub stance') and have a tucked up abdomen. Dysphagia is evident and the gut is empty except for the colon and rectum which contain dry, hard feces. In the late stages the patient snores, the penis droops, and attempts are made to eat abnormal materials. Most cases of the chronic form have rhinitis, characterized by crusting of mucopurulent material on the turbinates and this is considered, in the presence of appropriate history and other clinical signs, almost pathognomonic for grass sickness.

Application of phenylephrine (0.5 mL of a 0.5% solution) into one eye causes a dorsal deviation of the eyelashes of the upper eyelid in horses with grass sickness, but not in normal horses.[27]

There is a radiological discernible defect in esophageal motility in horses with grass sickness.[28]

Recurrence of the disease in a horse is exceedingly rare.

CLINICAL PATHOLOGY

Serum biochemical profiles and hematological examinations do not demonstrate pathognomonic changes.[29] Signs of dehydration, electrolyte imbalances, hyperbilirubinemia, and elevations of serum activity of liver derived enzymes are all secondary to the disease.[30] Urine from horses with grass sickness has higher specific gravity, protein and creatinine concentrations, and lower pH than that from unaffected horses,[31] consistent with dehydration and electrolyte imbalances that occur with the disease. Peritoneal fluid is often abnormal, having an increased protein concentration and leukocyte count but, because of the considerable overlap with values in horses with lesions of the gastrointestinal tract requiring surgery, is of limited diagnostic value.[32]

Antemortem diagnostic confirmation can only be achieved by examination of biopsy specimens of the ileum,[33] although biopsy of nasal mucosa has been suggested as an alternative.[18] Examination of rectal biopsy is specific, but not sensitive, for the disease.

NECROPSY FINDINGS

In cases of short duration, the stomach and small intestines are distended with an excess of fluid and gas, and the colon is often impacted with corrugated ingesta coated with black material. In chronic cases, the alimentary tract is empty.

Histologically there is extensive degeneration of neurons of the autonomic nervous system without evidence of inflammation.[33] These neurons include those of the ganglia (cranial cervical, stellate, coeliaco-mesenteric, etc.) and those of the myenteric and submucosal plexi of the intestines. Degenerative neuronal changes may also be observed in the central nervous system, including the oculomotor, facial, lateral vestibular, hypoglossal and vagal nuclei, the ventral horns of spinal cord and the dorsal root ganglia. This neuropathy is difficult to confirm unless fresh, well-fixed samples are submitted for histological examination. Immunohistochemical staining for synaptophysin aids in the differentiation between autolytic tissue and tissue from horses with grass sickness.[34]

Samples for post-mortem confirmation of diagnosis
Samples for light microscopic examination: formalin-fixed sympathetic ganglia, brain stem, spinal cord with dorsal root ganglia, gastric fundus, duodenum, jejunum, distal ileum, ventral colon, and dorsal colon.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:
Acute grass sickness

- Small intestinal strangulation or volvulus
- Large colon torsion
- Anterior enteritis
- Peritonitis
- Terminal ileal impaction
- Ileocecal intussusception.

Subacute or chronic grass sickness

- Impaction of the large or small colon
- Helminthiasis
- Mesenteric abscessation or other chronic inflammatory disease
- Gastric squamous cell carcinoma
- Alimentary lymphosarcoma or other neoplasia
- Inadequate diet
- Poor dentition
- Equine motor neuron disease.

TREATMENT

Acute cases respond transiently to gastric decompression and intravenous fluid administration, but death is inevitable. Selected chronic cases may benefit from careful nursing care and the administration of the promotility, indirect acting cholinergic agent, cisapride (0.5–0.8 mg/kg orally every 8 hours for 7 days).[35] Administration of brotizolam (a putative appetite stimulant), acetylcysteine (antioxidant and neuroprotectant), and aloe vera gel (antioxidant, anti-inflammatory and laxative) was without beneficial effect in 29 cases.[36]

CONTROL

Successful measures have not been satisfactorily established and no definitive recommendation can be made. However, consideration should be given to the factors identified as increasing the risk of disease, such as pasturing, movement to new properties and especially those on which previous cases of this disease have occurred, and the disturbance of soil. Feeding of hay and haylage is associated with a reduced risk of developing the disease. Although administration of ivermection is associated with an increased risk of the disease, appropriate parasite control should not be ignored in horses in areas in which grass sickness is endemic.

IDIOPATHIC CHRONIC INFLAMMATORY BOWEL DISEASES OF HORSES

A syndrome of combinations of weight loss, ill thrift, diarrhea, intestinal malabsorption, and hypoproteinemia attributable to chronic inflammatory disease of the small and/or large intestine of horses is well described. The syndrome has been subdivided into granulomatous enteritis, eosinophilic enteritis, lymphocytic-plasmacytic enterocolitis, basophilic enterocolitis, and multisystemic eosinophilic epitheliotropic disease.[1] Other causes of chronic inflammatory bowel disease in horses include alimentary lymphosarcoma, tuberculosis, pithyosis, and histoplasmosis.[2]

GRANULOMATOUS ENTERITIS OF HORSES

The etiology of granulomatous enteritis is unknown. Infection with *Mycobacterium* spp. is suggested as a cause but demonstration of acid fast bacteria in tissue sections or by culture of gut or mesenteric lymph nodes of affected horses is rare and inconsistent. The disease occurs with greatest incidence in Standardbred horses between 1 and 6 years of age, although it does affect other breeds of horses. The disease is usually sporadic, although it has been recorded in siblings raised on the same farm.[1] Estimates of incidence are not available. The disease has an almost 100% case fatality rate.

Accumulation of lymphocytes and multinucleated giant cells in the lamina propria is associated with villous blunting in the small intestine. There is malabsorption of carbohydrates and fats and excessive loss of protein in feces[2] with subsequent hypoalbuminemia, edema, and weight loss. Weight loss and anorexia are the most common presenting signs. Fever is uncommon. Approximately one-third of horses have diarrhea or a history of abdominal pain. Affected horses may have a diffuse, scaling alopecia and excoriations especially of the coronary band. Rectal examination may reveal enlarged, soft mesenteric lymph nodes. Exploratory laparotomy in horses with signs of colic attributable to inflammatory bowel disease often reveals constricting circumferential bands in the large or small intestine.[3]

Hematological and serum biochemical examination reveals:

- A mild, macrocytic **anemia** (hemoglobin <100 g/L, hematocrit <30%) with a normal leukogram
- Hypoalbuminemia is a consistent finding (<25 g/L, <2.5 g/dL) while the globulin concentration may be normal, low or, more commonly, high (>50 g/L, >5.0 g/dL)
- Plasma fibrinogen concentration is usually increased (>4 g/L, 400 mg/dL)
- There are no characteristic changes on serum biochemical analysis
- Peritoneal fluid is normal.

Absorption tests using (D(+)-xylose, glucose, or starch) may indicate diminished absorption of carbohydrate by the small intestine. The **D(+)-xylose absorption test** is performed by administering D(+)-xylose at a dose of 0.5 or 1 g/kg as a 10% solution by nasogastric intubation after an overnight fast. The concentration of D(+)-xylose in blood samples collected at 0, 1, 2, 3, 4, and 5 hours after dosing is determined. An abnormal test is one in which there is not an obvious peak in the D(+)-xylose curve and in which the peak concentration is lower than expected for a normal horse on a similar diet. Administration of a 10% glucose solution orally at a dose of 1 g/kg body weight results in an increase in plasma glucose concentration of >85% the baseline values in horses with normal small intestine. An increase of <15% over baseline is found in horses with small intestinal disease that impairs

glucose absorption. Intermediate values are found in both normal and diseased horses.[4]

Diagnostic confirmation is achieved by histological examination of biopsy of rectum or small intestine. **Rectal biopsy** has a low sensitivity (less than 50%) but high specificity for diagnosis of granulomatous enteritis.[5] **Biopsy of small intestine** and mesenteric lymph nodes has a much higher sensitivity than rectal biopsy and is the recommended test.

NECROPSY FINDINGS

Necropsy examination reveals that the intestinal wall is thickened uniformly especially in the jejunum and ileum. Mesenteric lymph nodes may be enlarged. There is villous atrophy with a diffuse and patchy granulomatous infiltration of the lamina propria of the small intestine. Crypt abscesses are common. Granulomas are also present in the liver, spleen, kidney, and bone marrow of many cases. The predominant cell types are macrophages and epitheliod cells with occasional giant cells. The disease may be difficult to distinguish from alimentary lymphosarcoma.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes:

- Parasitism
- Poor nutrition or dentition
- Alimentary lymphosarcoma
- Basophilic enterocolitis
- Eosinophilic enteritis
- Intrabdominal abscessation
- Gastric squamous cell carcinoma
- Small intestinal adenomatous polyposis.[6]

TREATMENT

Attempts at treatment with a variety of anti-inflammatory and antimicrobial drugs, including prednisone and sulfasalazine, have been almost university unsuccessful.[7] Resolution of the disease occurred for up to 7 months while a horse was treated with a decreasing dose of dexamethasone, beginning at 40 mg (0.1 mg/kg) intramuscularly every 4 days for 4 weeks, and then slowly decreasing.[7] Surgical resection of defined, solitary lesions is reported but this is an unusual manifestation of the disease.

CONTROL

There are no effective control measures.

LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

This is an uncommon disease of horses, in contrast to dogs, affecting horses of any age and without discernible breed or sex predilection.[1,2] The etiology is unknown. Presenting signs include weight loss, diarrhea, and lethary. Clinicopathologic abnormalities include hypoproteinemia and hypoalbuminemia in approximately one-half and three-quarters of cases, respectively.[2] Results of an oral glucose tolerance test are abnormal in approximately 75% of cases. Histologic examination of a rectal mucosal biopsy reveals abnormal tissue suggestive of the disease in about one-half of cases. The diagnosis is confirmed by biopsy of ileum or necropsy examination. Differential diagnoses are similar to those for granulomatous enteritis. There is marked infiltration of the lamina propria with lymphocytes and plasma cells. Effective treatment has not been described. Control measures are not available.

CHRONIC EOSINOPHILIC GASTROENTERITIS OF HORSES

Eosinophilic enterocolitis occurs either as part of the multisystemic, eosinophilic, epitheliotropic disease complex or as a lone entity. Multisystemic, eosinophilic, epitheliotropic disease is characterized by eosinophilic infiltrates in the gastrointestinal tract and other organs, while horses with eosinophilic enterocolitis have no evidence of extraintestinal disease.

Multisystemic, eosinophilic, epitheliotropic disease occurs in adult horses of any age and without apparent breed or sex predilection. The etiology is unknown, but some cases are associated with lymphosarcoma, suggesting that the disease in these horses is due to clonal expansion of a T-lymphocyte population that secretes interleukin-5.[1] The disease is idiopathic in most horses. Clinical signs include weight loss in all cases and diarrhea or dermatitis in approximately two-thirds of cases.[2] The dermatitis occurs mainly on the face, limbs, and ventral abdomen and is exudative with alopecia, hyperkeratosis, and lichenification.[3] Lesions of the coronary band and mouth are common. Urticaria occurs in some horses. Most affected horses have low serum protein and albumin concentrations. Hypereosinophilia is not a consistent feature of the disease and blood leukocyte concentrations are usually within the reference range. There are often elevations in serum activity of gammaglutamyl transpeptidase (GGT) and alkaline phosphatase, consistent with lesions in the biliary tree. This can be useful in differentiating horses with this disease from horses with granulomatous enteritis.[2] Histologic examination of tissues reveals eosinophilic infiltration of skin, liver, and gastrointestinal tract. Rectal biopsy can reveal the presence of eosinophilic granulomas, but these must be differentiated from the more common eosinophilic infiltrate secondary to parasitism. Treatment is usually ineffective and the prognosis for recovery is very poor. Affected horses should be administered an anthelmintic in case the disease is due to nematodiasis. Administration of corticosteroids (dexamethasone, prednisolone) is the usual treatment but is only transiently effective in most cases. Hydroxyurea, which is used to treat a similar syndrome in people, was only transiently effective in one horse.[4] There are no recognized control measures.

Idiopathic eosinophilic enteritis is a sporadic disease of horses of any age. Affected horses rarely have weight loss or diarrhea.[2] The common form of the disease is one in which the infiltration is segmental and associated with acute colic due to obstruction of the small intestine or large colon by mural lesions.[5,6] The D(+)-xylose absorption curve is usually normal in affected horses.[7] Histologically, the disease is characterized by the presence of eosinophilic infiltrates in a chronic inflammatory reaction affecting the small or large intestines. The infiltrates are restricted to the intestinal tract. The cause has not been identified but the lesion suggests a continuing hypersensitivity reaction to an ingested allergen. Antemortem diagnostic confirmation is achieved by rectal or small intestinal biopsy. Successful treatment is usually surgical. Control measures are not reported.

OVINE MOUTH AND GUM OBSCURE DISEASE (OMAGOD)

During the outbreak of foot-and-mouth disease (FMD) in the UK in 2001, field investigations reported the appearance of oral lesions, initially in sheep and then in cattle which complicated the diagnostic process.[1,2] While the lesions appeared to have a common, though obscure, etiology, prior to that they had not been identified as a differential diagnosis for FMD. The lesions were usually singular, located predominantly (but not exclusively) in the gingival mucosa ventral to the incisors, often in the midline; circular to nearly circular in shape and usually ranging in

diameter from 4 to 10 m; never vesicular but always erosive with a raised edge, giving the ulcer a crater-like appearance; and were more prevalent in adult sheep than in lambs.[2]

Experienced sheep veterinarians in the UK have reported ulceration of the gums of sheep as a regular occurrence in late winter and spring.[1] It has been suggested that grazing sparse rough or short pasture, the provision of feed or salt blocks, and the use of feeding troughs with sharp edges, could be predisposing causes.

An abattoir survey of sheep in New Zealand examined the lesions of the anterior lips and gums of the animals after slaughter.[3]

Lesions of the midline of the lips and gums of traumatic or irritant etiology were common, and the prevalence was higher in adult sheep than in lambs. The lesions probably arose from the fright/flight response behaviour of sheep, resulting in the mouth impacting against wire fences or yard railings while being handled. A smaller percentage of lesions may have been due to abrasive or irritant feed or soil. The presence of plant material and bacteria in lesions delayed healing and contributed to the formation of ulcers.

ULCERATION OF THE *PARS ESOPHAGEA* OF THE STOMACH OF SWINE (GASTRIC ULCER, HYPERKERATOSIS)

Naturally occurring ulcers of the stomach in swine occur in the *pars esophagea* (non-glandular part) of the stomach. They are single or multiple bleeding ulcers often associated with hyperkeratosis. Experimental lesions in the stomach are usually produced in the glandular part of the stomach as a model for the condition in humans. The condition was first reported in Illinois in 1897.

Synopsis

Etiology Fine particle and pelleted feed. Certain bacterial species may contribute.
Epidemiology Highly variable incidence but has increased with greater intensification of swine industry, emphasis on improving digestibility and feed efficiency and use of fine particle and pelleted feed. Growing and finishing pigs, adult sows, and boars.
Signs Sudden death from peracute gastric hemorrhage. Subacute form causes anemia, pallor, unthriftiness, black tarry feces.
Clinical pathology Hemorrhagic anemia.
Lesions Hyperkeratosis, erosions, ulcers of *pars esophagea*, gastric hemorrhage, anemia.
Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
- Proliferative enteritis of swine
- Enteric salmonellosis
- Swine dysentery.

Treatment None.
Control Use of diets prepared through hammer mill screen of at least 6 mm. Incorporate S-methylmethionine-sulphonium chloride in diet.

ETIOLOGY

The etiology is multifactorial. Finely ground and pelleted feed are important causes. *Helicobacter heilmannii*[1] and *Gastrospillium suis*,[2] have been found in gastric ulcers, but not ulcers of the *pars esophagea* of pigs and are unlikely to be the primary cause of the lesion.[3] Certain environmental stressors may also be contributing factors.

EPIDEMIOLOGY

Occurrence

The disease is most common in pigs of 45–90 kg BW[4] but the disease may also occur in pigs after weaning and in adult sows and boars. All breeds are susceptible. Prevalence in groups of pigs may vary anywhere in the world from 5 to 90%. In some countries the rate is 1% and in others 87%.[5]

Most gastric ulcers of pigs are localized in the *pars esophagea* and are referred to as esophagogastric ulceration. Examination of the stomachs of pigs at abattoirs in various countries has revealed a high proportion of pigs with varying degrees of hyperkeratosis, erosions, and ulcers of the *pars esophagea*. Extensive erosions of the *pars esophagea* may be present in up to 63% of sows and 36% of finishing pigs.[6]

The incidence is variable between countries which may reflect differences in feeding or husbandry methods. In the Netherlands 11% of the pigs may be affected.[7] The incidence of ulceration may be increasing in pigs in the UK compared to earlier studies.[8] An abattoir survey of the stomachs of pigs in the UK found ulceration of the *pars esophagea* in 23% with a range from 4 to 57%.[8] The ulcers were mild in 9.5% and severe in 13.4%.

The disease has assumed increased economic importance with increased intensification of the swine industry.[9] The feed manufacturing industry is faced with the dilemma of finely ground pelleted feed providing high digestibility and feed efficiency in growing and finishing pigs but with a high incidence of lesions of the *pars esophagea* which may affect performance. Pelleting swine feed is also advantageous because it flows more easily and effectively in automated distribution systems in swine farms compared to finely ground meal which may bridge and clog in distribution systems, decrease dustiness and segregation of ingredients and increase bulk density. Meal is less damaging than pellets.

The incidence of clinical disease is low but the case fatality rate is high when severe hemorrhage occurs. The effects of the lesions on performance may vary considerably. In one study, pigs with extensive lesions gained 50–75 g/day less than pigs with no lesions[10] while in another the presence of ulcers as determined at the abattoir did not influence growth rate.[8] The disease has increased in significance with the occurrence of PMWS and PDNS associated with porcine circovirus 2. There is also an increased occurrence where there is a problem with porcine respiratory disease complex (PRDC) particularly during summer months.

Risk factors

Anything that causes an empty stomach which potentially increases the acidity in the *pars esophagea* region of the stomach is a risk factor.[7] Back in the 1960s all that was needed to produce an esophageal ulcer in a pig was to keep the pig restricted in a feeding or farrowing crate and deprive it of water for 24 hours and it would have an ulcer. This would therefore include intermittent feeding and watering, respiratory disease and hot weather.

Dietary risk factors

The disease occurs primarily in penned pigs receiving a grain diet and growing rapidly. It has also occurred in pigs fed large quantities of cheese whey or skimmed milk. Too much copper and not enough zinc may also be a factor. The incidence is highest in pigs receiving diets containing a higher proportion of corn (maize) than other grains. The incidence is even greater if the corn is finely ground or is gelatinized or expanded. Ulceration in some pigs may be associated with *Ascaris suis* infection, but in other studies there is no significant association between the parasite and ulcers.

Finely ground feed

This is the most important risk factor.[11] One of the explanations of this may be the rapid emptying of the stomach when fine particles are used.[12] There is normally a gradation of ascending pH from the cardia to the oesophagus but with rapid emptying there is the possibility of the low pH reaching the esophageal region.[11,12]

Feeding a diet based on finely ground barley to pigs beginning at 10–11 weeks results in lesions as early as 1 month later, and the incidence and severity of lesions increased progressively over the next

2 months. Diets high in wheat or corn starch may be worse than diets based on barley. The incidence and severity of hyperkeratosis may be greater in some breeds compared to others, but the effects of previous diets and environmental factors may have influenced the results.

The particle size and the physical form of the feed are important risk factors. Finely ground diets and pelleting have detrimental effects on the gastric mucosa of finishing pigs.[13] A pelleted diet uses grain that is finely ground before it is compressed into a pellet but on reaching the stomach it reverts to the fine particles. A diet finely ground through a 3 mm screen in a hammer mill and then pelleted will be associated with a 75% incidence of pigs with hyperkeratosis of the *pars esophagea* and 11% of the pigs may have severe erosions and ulceration of the *pars esophagea*.[10] The incidence of lesions decreases when the diet is ground through a 6 mm screen.[14] Finely ground barley or wheat is associated with a marked increase in gastric abnormalities compared to the use of coarsely ground grains. The size of particles in feed is significant whatever feed is used, even straw; coarsely ground barley straw at 5–10% of the ration gives almost complete protection. In growing pigs, dietary fiber rich in structural polysaccharides has been shown to be important in preventing the development of parakeratotic lesions in the *pars esophagea*.[15] But an increase in the crude fiber content of a diet which is finely ground does not affect the occurrence of severe erosions and/or ulcers of the *pars esophagea*.

Grinding barley through a 1.56 mm screen results in finely ground feed, which is associated with an increased incidence and severity of gastric ulcers in pigs. Grinding through a 4.68 mm screen approximates the screen size used most frequently for grinding barley for pigs in practice and is associated with a low incidence of ulcers.[15]

Reducing particle size and pelleting improves growth performance of finishing pigs.[16] For every 100 microns of decrease in size of the particle size there is an approximately 1.3% increase in gain efficiency but each time the level of ulcers increases.[17] The processes have additive effects on digestibilities of dry matter, nitrogen, and energy, with maximum nutrient digestibility in pelleted diets with corn milled to a particle diameter size of 400 µm. Reducing the particle size to below 400 µm causes practical problems with milling and an increased incidence of gastric lesions and it is suggested that a particle size of 600 µm, or slightly less, is optimal for corn in either meal or pelleted diets for finishing pigs.

Using endoscopic examination of the stomachs of pigs fed a fine particle diet (geometric mean size of 578 µm) it was found that as ulcer severity increases, the growth performance of individually fed pigs decreases. Feeding a coarse particle diet (geometric mean size of 937 µm) for 3 weeks resulted in a decrease in the severity of the ulcers.[18]

High levels of unsaturated dietary fat are not helpful especially if they are accompanied by low levels of vitamin E. Similarly pigs fed waste food had more severe gastric lesions.[19]

Environmental and management risk factors

It has been suggested that confinement, crowding, transportation, changes in environment, and exposure to other pigs, were important in the etiopathogenesis of gastric ulcers of pigs. All of these stresses and many others including anxiety, fear, pain, fatigue, fasting, etc., will be associated with an increase of ulcers. There is an even greater occurrence in summer when water demands are higher. Males are always more affected in prevalence and severity but that may be that they are more easily stressed. One of the most important factors is time in the lairage. Pre-mortem handling is extremely important.[20] Pigs kept overnight in the lairage have more ulcers than pigs killed on the day of arrival.[21] Similarly there is no difference in the prevalence of lesions in small and medium farms but there is a considerable increase in the prevalence in these two groups compared to the larger producer.[22] Larger herds always show more of the problem[23] and it is probably a reflection of the different diets that they use (based on wheat and pelleted). The larger farms also have more infection pressure, more selection pressure, and more feed-related factors.

Pigs that receive porcine somatotrophin may have an increased level of ulcers possibly due to the elevated circulating gastrin.[24]

There are a variety of foreign bodies reported from the pigs' stomach including stones, which outside sows chew all the time, and also sand. The majority of stones is probably passed in the feces, but may accumulate in and stretch the stomach. The stomach capacity is normally about 3–6 L. This may lead to reduced appetite and gastritis but is not believed to be a contributor to esophageal ulceration. Similarly, hairballs are a common finding, reaching 10–15 cm in size in the stomach. The occurrence of rubbish indicates pica or a depraved appetite which is often an indicator of inadequate feeding. One of the other substances found in outdoor pigs stomachs is the flakes of bitumen that remain from clay pigeon shooting, which are toxic.

Increased frequencies of any of four combinations of behavioral indicators of stress, recorded 4 weeks after weaning, were weakly associated with increased risk of acute fundic ulcers in slaughter pigs from a conventional farrow-to-finish herd.[25]

Pathogen risk factors

Gastric bacteria

The spiral-shaped *Gastrospirillium suis* has been found in 84% of the stomach of pigs with frank gastric ulcers of the *pars esophagea*. The organisms were mainly in the mucus layer and in gastric foveolas of the antral and oxyntic mucosa and only occasionally in the cardiac-*pars esophagea* region.[2] The presence of the organism has been associated with lesions of the pyloric mucosa in pigs.[26]

There is no known cause and effect relationship but the gastric environment associated with gastric ulcer may favor colonization of the organism. The oral inoculation of *Gastrillium*-like bacteria into laboratory animals is capable of inducing gastric ulceration.[27] *Helicobacter heilmannii* type 1[28] has been found more frequently in the stomachs of pigs with ulcers (100%) and in those with pre-ulcer lesions (90%) than in stomachs with macroscopically normal *pars esophagea* (35%).[1] It has been suggested that *Helicobacter heilmannii* may play a role in the pathogenesis of gastric ulcers in swine by causing increased acid secretion. *H. pylori* can colonise the pig stomach. Experimental reproduction of *Helicobacter suis* infection has recently been described.[29] The pigs had no ulcers and infection was only accompanied by a mild superficial gastritis.

PATHOGENESIS

In pigs, nearly all naturally occurring gastroduodenual ulcers are localized in the *pars esophagea* of the stomach. Excessive gastric acid production, depletion of the gastric buffering system resulting in prolonged activation of pepsinogens, and changes in mucus composition are suggested as important factors related to gastric ulceration in swine. The physical texture of the feed can influence pepsin and acid secretion, and the fluidity of the stomach contents induced by ulcerogenic diets may alter the normal pH gradient within the stomach. This allows greater pepsin and acid contact to the esophagogastric area.

The concentrations of short chain fatty acids are high in the proximal gastric contents of pigs and associated with intakes high in readily fermentable carbohydrates, like ground corn. These products of bacterial metabolism, principally acetate and lactate, reach high concentrations within 4 hours after feeding because of high pH

in the proximal gastric contents which may allow some types of bacteria to proliferate. These weak acids are lipid soluble in their undissociated form and could penetrate and acidify underlying tissue more readily than free hydrogen ions. In this way, rapid production of short chain fatty acids, followed by their absorption and tissue acidification, may be similar to ruminal acidosis and rumenitis in ruminants following the ingestion of large quantities of readily fermentable carbohydrates.[30]

The rumen epithelium, also a stratified squamous mucosa, is easily injured by short chain fatty acids at pH ≤ 5.0. The breaking of the barrier by short chain fatty acids could result in underlying inflammation and widespread tissue destruction. Experimentally, exposing undissociated short chain fatty acids to swine gastric mucosa results in rapid penetration of the outer barrier and acidification of the underlying viable tissue.[30] This results in cell swelling and vesicle formation, followed by sloughing of the outer barrier, erosion into deeper zones, and finally, ulceration.[30]

Weak organic acids, at pH ≤ 2.5 induce a greater degree of functional and histological injury in 3 stomach zones (squamous, cardiac, and oxyntic) than does hydrochloric acid. The predilection for the squamous mucosa in naturally occurring ulcers may be attributed to the lack of defense or repair mechanisms that are present in the cardiac and oxyntic mucosa, which are capable of HCO_3- and mucus secretion, which may raise the pH adjacent to these epithelial layers.[30] Thus the increased digestibility associated with decreased particle size of the diet may promote rapid fermentation following eating resulting in the production of increased concentrations of short chain fatty acids. Any increase in fluid content will also contribute to the changes in pH gradient that exist in the stomach. Excessive gastrin is then stimulated and more acid secretion follows.

Normally, the *pars esophagea* is white, smooth, and glistening and may be bile stained. The first stage in ulceration is hyperkeratosis. This is followed by erosions, ulcerations, and hemorrhage. The erosions may heal, resulting in a fibrous contraction. Chronic ulceration may occur with the development of several ulcers in combination with fibrous tissue involving all of the squamous mucosa. Advanced hyperkeratosis may cause partial stenosis of the terminal esophagus.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach.

The regurgitation of bile into the stomach and the intensity of bile staining of esophagogastric tissue have been linked to the pathogenesis of esophagogastric ulcers in pigs. Almost all stomachs of pigs contain bile and bile staining of the *pars esophagea*; there is no evidence for the hypothesis that the regurgitation of bile into the stomach is associated with esophagogastric lesions in finishing pigs.[31] There is no evidence of an association between gastritis and ulcer.[32]

CLINICAL FINDINGS

Most cases are sub-clinical but sows will die from blood loss. Pigs frequently die from ulcers during concurrent disease such as respiratory disease[33] and in this case anorexia may disturb the gastric contents and allow material of high acidity to reach the cardia. Similarly where there is a reduced consumption of water the integrity of the mucus may be broken by the dessication that results on mucosal surfaces.

Gastric ulceration is most common in pigs over 6 weeks of age and occurs in adult sows and boars; the clinical findings are dependent on the severity of the ulcers. The effects of ulceration on production may be highly variable. Most pigs with esophagogastric ulcers are clinically normal, and growth rate and feed intake appear unaffected. Some observations suggest that there is no effect of ulceration on growth rate, while others indicate that the presence of esophagogastric ulcers results in a marked decrease in growth rate and an increase in the length of time required for the pig to reach market weight. Some affected pigs also eat slowly and regurgitate frequently. Endoscopic monitoring of the stomachs of pigs fed ulcerogenic diets found that as the severity of the ulcer increased growth performance was decreased.[18] The greatest economic losses were associated with sudden deaths due to hemorrhage and marked decreases in performance associated with fine particle size.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach. When pigs are found dead from peracute hemorrhage, inspection of the in-contact pigs may reveal other animals with pallor and black tarry feces which represent those with subacute hemorrhage.

Cases with subacute gastric hemorrhage may survive for a few days and there is evidence of marked pallor, weakness, anorexia, and black pasty feces changing to mucus-covered pellets in small amounts. The weakness may be sufficient to cause recumbency. Vomiting frothy bile-stained fluid and grinding of the teeth may occur. Abdominal pain may be elicited by deep palpation over the xiphisternum and there may be a reluctance to walk along with a rigid back indicative of pain.[6] Animals that survive are often unthrifty, usually due to anemia from chronic blood loss with a few cases affected by chronic peritonitis. When the disease is occurring careful observation may detect early cases. Suggestive signs are a darkening of the feces and the development of pallor.

CLINICAL PATHOLOGY

Laboratory testing is not indicated. Animals with gastric ulceration generally have lower hematocrit values, haemoglobin concentrations, and erythrocyte counts than normal. The black tarry feces can be examined for the presence of blood.

NECROPSY FINDINGS

Ascarids have been found in the stomach but these are not a factor in the field.[34]

At necropsy, the ulcers are confined to the esophageal region of the stomach. Affected stomachs consistently have more fluid contents than unaffected ones. If severe blood loss from the ulcer has been the cause of death then the carcass is pale and fresh blood is usually present in the stomach (there may be large blood clots) and intestines. The colonic contents may also appear melenic. Early lesions in clinically unaffected animals include hyperkeratinization of the mucosa (usually pale raised areas without bile staining initially) which progresses to epithelial erosion without actual ulceration. Ulcers usually initially occur along the junction of the *pars esophagea* with the glandular stomach but may enlarge to efface the entire squamous portion of the stomach. These more diffuse ulcers are easily missed on cursory examination due to their uniform appearance. Chronic gastric ulcers develop thickened, raised edges due to ongoing fibrosis, occasionally resulting in a gastroesophageal stricture. The histological appearance varies with the stage of lesion development but in fatalities there is typically complete loss of the epithelial layer, with exudation of neutrophils from a bed of mature granulation tissue. Recent studies have demonstrated *Helicobacter*-like bacteria in porcine stomachs but further research is required to determine if this infection plays a significant role in ulcer formation. Small clusters of *H. hellmanii* have been seen in the gastric crypts,[35] but are not associated with histological changes.[36] A recent survey suggested no correlation between infection

in the cardiac mucosa and the severity of the lesions shown by the esophagogastric region.[37] The macroscopic findings are usually sufficient for the confirmation of a diagnosis of esophagogastric ulceration. The initial lesion of hyperkeratosis leads to parakeratosis with fissures and the lamina propria is then exposed. The epithelium sloughs off and then ulcers of the epithelium develop with haemorrhage from the vessels.

Severity and extent of esophagogastric lesions can be graded according to the following scheme[6]:

0: intact epithelium
1: small degree of hyperkeratosis (< 50% of total surface)
2: distinct hyperkeratosis (= 50% of the total surface)
3: hyperkeratosis and less than 5 erosions smaller than 2.5 cm in size
4: hyperkeratosis and more than 5 erosions or erosions larger than 2.5 cm in size
5: hyperkeratosis and more than 10 erosions or erosions larger than 5 cm in size, and/or an ulcer (with or without bleeding) or stenosis of the esophagus towards the stomach.

No difference in lesion score was found between Duroc, Landrace, and Iberian pigs.[38]

DIFFERENTIAL DIAGNOSIS

The occurrence of sudden death with a carcass that shows extreme pallor and a marble-white skin suggests the possibility of peracute hemorrhage from an esophagogastric ulcer. The disease must be differentiated at necropsy from proliferative hemorrhagic enteropathy, swine dysentery, and salmonellosis. Black tarry feces in growing and finishing pigs are characteristically due to subacute hemorrhage associated with esophagogastric ulceration.

It is possible to detect stomachs with Helicobacters by covering the stomach with urea gel containing an indicator sensitive to pH change. If there are large numbers of urease-positive bacteria then the pH changes.[39]

Severe infestation with whipworms is a differential. The clinical diagnosis can be confirmed by endoscopy[40] which requires an empty stomach (may cause ulceration in itself) and anesthesia.

TREATMENT

Vitamin K and hematinics have been tried with little success. Bovine serum concentrate given as a 1% solution is supposed to have reduced the extent and severity of signs associated with ulcers in growing pigs but in general medication does not help.[41] If a diagnosis is made euthanasia is advised.

CONTROL

Control of esophagogastric lesions of growing and finishing pigs is dependent on using diets with a particle size and physical form which will provide the most economical performance in terms of digestibility and feed efficiency and minimize the incidence of lesions.

The most desirable particle size or physical form of diet, meal, or pelleted form, has not been determined. The use of a diet ground through a 6 mm screen instead of 3 mm screen is recommended. However, screen size is not the only factor affecting particle size. Other factors include the condition of the screen and hammer, the type and variety of grain and its moisture content, the speed of the mill, the pelleting process and the flow rate in the distribution of the feed to the pigs. A particle size of 600 µm, or slightly less is suggested as optimal for corn in either meal or pelleted diets for finishing pigs.[16]

The incorporation of S-methyl-methionine-sulphonium chloride (MMSC), a nutritional component of many vegetables such as cabbage and carrots, has anti-gastric ulcer properties. Its addition to the diet, ground through a 3 mm screen, and fed to grower pigs from 45 to 107 kg liveweight, at 400 ppm decreased the incidence of severe erosions or ulcers by about 50%.[14] The addition of lucerne meal to increase the crude fiber content of one of the experimental diets did not have an effect on the incidence or severity of the lesions.

The diet should contain adequate amounts of vitamin E and selenium. Where applicable a reduction of the amount of corn in the ration and the feeding of meal rather than pellets may also be of value. The reduction of environmental and managemental stressors with attention to stocking rates may be of value.

CHRONIC INFLAMMATORY BOWEL DISEASE OF SHEEP

This syndrome of unknown etiology is manifest with wasting, ill thrift and mortality, or culling for poor production, and is reported in England and Canada.[1,2] It affects both housed and pastured sheep predominantly in their first year of life, but cases up to 3 years of age have been seen. Affected sheep are dull and anorectic with pale mucous membranes and have fecal staining of the perineum. The rumen fill is reduced and the feces are soft and malodorous. Blood examination shows hypoalbunimemia, an elevated blood urea nitrogen, and leukocytosis with neutrophilia. On post mortem there is lymphocytic enteritis with gross thickening of segments or the entire or distal part of the small intestine. There is no evidence for Johne's disease or parasitic gastroenteritis and the syndrome has similarities to the proliferative enteropathies of swine and horses.

Diseases characterized by respiratory tract involvement

INTERSTITIAL PNEUMONIA OF CATTLE

Interstitial pneumonia of cattle has been known for many years under many different terms including: atypical interstitial pneumonia, acute pulmonary emphysema and edema, bovine pulmonary emphysema, 'panters', 'lungers', bovine asthma, pneumoconiosis, and 'fog fever'.

Diffuse or patchy damage to alveolar septa is the essential feature of interstitial pneumonia which may be acute or chronic and can be caused by many forms of pulmonary injury. There is an obvious lack of lesions of the small airways which differentiates interstitial pneumonia from bronchopneumonia. Traditionally it was thought that interstitial pneumonias were characterized by chronic inflammation in which there is a predominantly proliferative response involving the alveolar walls and supporting stroma. However, acute diffuse damage of the alveolar walls accompanied by an early intra-alveolar exudative phase, which can be followed by proliferation of type 2 alveolar epithelial cells and fibroblasts, is now commonly recognized.

The recognition that interstitial pneumonia can have an acute exudative phase was the reason for the designation of acute interstitial pneumonia in cattle as 'atypical' interstitial pneumonia. The use of the word 'atypical' may create some confusion in the interpretation and diagnosis of lesions and in the conveying of information. It may be more appropriate to use the term interstitial pneumonia and specify where possible, clinically, epidemiologically, and pathologically the various forms of interstitial pulmonary disease in cattle.

The diseases in which interstitial pneumonia is the essential lesion are listed in Table 36.1. Pulmonary congestion and edema, alveolar exudation, hyaline membrane formation, interstitial emphysema, and alveolar epithelial cell hyperplasia and fibrosis of the supporting stroma without lesions of the smaller airways are the characteristic lesions, with their presence and extent varying according to the stage of the disease process.

The term atypical interstitial pneumonia as originally proposed is still useful in describing some of the diseases clinically and sets them apart from the common acute infectious diseases, especially the viral diseases of the respiratory tract of cattle. Clinically, they are atypical with regard to most clinical signs, especially when compared to the bacterial pneumonias:

- Some are acute, like fog fever, while others are chronic as in 'bovine farmer's lung'
- There is usually acute or chronic respiratory distress and a relative absence of toxemia
- Most are progressive and non-responsive to treatment
- Pathology consists of varying degrees of pulmonary emphysema, edema, hyaline membrane formation, and alveolar epithelial cell and interstitial tissue hyperplasia.

While there are obvious clinical, and particularly epidemiological, differences between the various diseases, there are fewer differences between the pathological findings which tend to merge from one to another.

Table 36.1 Diseases of the lungs of cattle in which the essential lesion is interstitial pneumonia

A. *Diseases of uncertain etiology*
1. Acute bovine pulmonary emphysema and edema (ABPEE) also known as 'fog fever', in cattle moved from dry to lush pasture (may be due to D,L-tryptophan). Usually occurs in outbreak form
2. Diffuse fibrosing alveolitis. Chronic disease which occurs sporadically in mature cows
3. Sporadic cases of acute interstitial pneumonia of young cattle (6–18 months of age). May be due to bovine respiratory syncytial virus or sequel to pneumonic pasteurellosis

B. *Hypersensitivity diseases*
1. Extrinsic allergic alveolitis (bovine farmer's lung). Epidemiologically associated with moldy feeds in housed cattle. May be sudden in onset in individual animals or develop insidiously as a chronic disease in several cows
2. Milk allergy. Occurs sporadically and is sudden in onset

C. *Plant poisoning*
1. *Ipomoea batatas* (sweet potatoes infested with the mold *Fusarium solani*)[3]
2. *Ziera aborescens* (stinkweed)
3. *Perilla frutescens* (purple mint)
4. *Brassica* spp.

D. *Parasitic diseases*
1. *Dictyocaulus viviparus* (including the hypersensitivity aspect)
2. *Ascaris suum*

E. *Exposure to irritant gases and fumes*
1. Nitrogen dioxide
2. Zinc dioxide

F. *Endotoxic or metabolic*
Shock lung due to endotoxemia such as in peracute coliform

Synopsis

Etiology D, L-tryptophan in forage. Inhalation of certain gases. Hypersensitivity to molds. Mycotoxicosis and plant poisonings. Viral and bacterial infections.

Epidemiology Primarily in adult cattle moved from dry to lush pasture. Outbreaks of acute pulmonary emphysema and edema occur primarily in adult cattle moved from dry to lush pasture in autumn in North America. In UK and Europe other interstitial pneumonias due to hypersensitivity to molds occur.

Signs Outbreaks of acute respiratory distress in pasture form of disease; severe dyspnea, mouth breathing, expiratory grunt, subcutaneous emphysema, and rapid death. Subacute form less severe and may survive but develop cor pulmonale later. Individual cases of interstitial pneumonia in UK and Europe are subacute and chronic.

Clinical pathology None clinically applicable.

Lesions Enlarged firm lungs which do not collapse, diffuse congestion and edema, interstitial and bullous emphysema, cranioventral consolidation, hyaline membrane formation, alveolar epithelial hyperplasia, fibrosis.

Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
- Pneumonic pasteurellosis
- Organophosphatic insecticide poisoning
- Nitrate poisoning
- Other interstitial pneumonias
- Bovine farmer's lung or extrinsic allergic alveolitis
- Lungworm pneumonia
- Verminous pneumonia caused by aberrant migration of *Ascaris suis* larvae
- Feedlot interstitial pneumonia
- Enzootic pneumonia of calves

Treatment None.

Control Grazing management. Use of antimicrobials to control conversion of tryptophan to 3-methylindole. Adequate housing and ventilation to control hypersensitivity pneumonias.

ETIOLOGY

There are several different possible causes.

Acute bovine pulmonary emphysema and edema (ABPEE) or fog fever

This is an acute atypical interstitial pneumonia also known as acute respiratory distress syndrome of cattle. The cause in adult cattle which have been moved from a dry to a lush pasture in the autumn season is related to the ingestion of a toxic level of D,L-tryptophan in the forage.[1] The experimental oral administration of toxic amounts of D,L-tryptophan to cattle causes clinical and pathological findings similar, if not identical, to those of the naturally occurring disease. D,L-tryptophan is converted in the rumen to 3-methylindole which, when given orally or intravenously, also produces the characteristic lesions in cattle and goats. The 3-methylindole exerts a direct effect upon cells and cell embranes of bronchioles and alveolar walls, perhaps as a result of strong lipophilic properties.

Specific forages have not been implicated, but affected cattle have often been consuming alfalfa, kale, rape, turnip tops, rapidly growing pasture grass, and several other feeds. However, pasture levels of tryptophan are not necessarily higher in those associated with the disease compared to normal pastures. In some naturally occurring cases of fog fever in beef cows changed from a dry summer range to a lush green pasture, there is a marked increase in the ruminal levels of 3-methylindole while in other cases the levels are not abnormal. Failure to detect abnormally high levels in the rumen and plasma of naturally occurring cases may be related to the rapid metabolism and elimination of 3-methylindole.

The levels of tryptophan in lush pasture are sufficient to yield toxic doses of 3-methylindole. A 450 kg cow eating grass at an equivalent DM intake of 3.5% of BW/day with a tryptophan concentration of 0.3% of DM would ingest 0.11 g tryptophan/kg BW/day. The total amount ingested over a 3-day period would approximate the single oral dose of 0.35 g/kg BW needed to reproduce the disease experimentally.

Diffuse fibrosing alveolitis

This is a chronic interstitial pneumonia of cattle which occurs sporadically and is suspected of being caused by repeated subclinical incidents of ABPEE or from recovered cases of the disease. Experimentally, repeated oral doses of 3-methylindole can result in diffuse pulmonary fibrosis and alveolitis in cattle.

Parasitic infestation

For many years it was thought that massive infestation of the lungs by large numbers of lungworm larvae in a lungworm-sensitized animal could cause an allergic reaction resulting in the development of acute bovine pulmonary emphysema. The possibility of such hypersensitivity as being associated cannot be totally ignored but at the present time there is no evidence to support such a theory. Such hypersensitivity may occur when the level of larval infestation of pasture is extremely high but it is not involved in the great majority of cases. In most cases of naturally occurring fog fever there is no laboratory evidence of lungworms in the lungs or feces of affected and in-contact animals. Reinfection of cattle with lungworm will occur 2–3 weeks following introduction to an infected pasture and cause acute respiratory distress which is indistinguishable clinically from fog fever. The migration of abnormal parasites, particularly *Ascaris suum*, has been observed to cause an acute interstitial pneumonia in cattle which were allowed access to areas previously occupied by swine.[1]

Inhalation of irritant gases

The experimental inhalation of nitrogen dioxide gas is capable of causing acute interstitial pneumonia in cattle[1] and severe alveolar edema and emphysema in pigs but it seems unlikely that animals of either species would be exposed naturally to a significant concentration of the gas for a sufficiently long period to produce such lesions.

Pigs which survived experimental exposure to silo gas did not have the lesions seen in silo-fillers' disease in man, and experimental exposure of cattle to nitrogen dioxide gas produces lesions which do not occur in naturally occurring fog fever. Acute pulmonary emphysema and deaths have occurred in cattle exposed to zinc oxide fumes produced by the welding of galvanized metal in an enclosed barn housing cattle.

Hypersensitivity to molds

The ingestion or inhalation of molds may be a cause of the disease in cattle.[1] The disease has been associated with hypersensitivity to moldy hay based on the presence of serum precipitins of the thermophilic antigens of *Thermopolyspora polyspora*, *Micropolyspora faeni*, and *Thermoactinomyces vulgaris* in cattle affected with extrinsic allergic alveolitis or bovine farmer's lung.

In Switzerland, a high incidence of serum precipitins against *Micropolyspora faeni* (60%) and moldy hay antigen (80%) was demonstrated in exposed but apparently healthy cattle from an area where 'allergic pneumonia' is common. The precipitins decreased during the pasture season and increased during winter housing.

Outbreaks of acute respiratory disease in adult cattle due to acute allergic pneumonitis can occur 15 hours after the introduction of severely moldy hay. Serological investigation and provocative challenge may reveal a hypersensitivity pneumonitis due to allergens of *Micropolyspora faeni*. A hypersensitivity pneumonitis has been produced experimentally in calves by exposure to aerosols of *Micropolyspora faeni* with or without prior sensitization by subcutaneous injection of the antigen.

In some Canadian cattle barns the disease occurred in cattle located near the hay chute from which hay and bedding are thrown down from the hay storage above the floor where the animals are kept. It has been suggested that the degree of exposure to dusty hay was greater in these cattle but that has not been substantiated. Similarly, it has been proposed that feeding finely ground feed may be associated with interstitial pneumonia in feedlot cattle but there is little evidence to support the observation.

The high incidence of ABPEE in the autumn when many legumes and other pasture plants are flowering, and the common occurrence at this time of allergic rhinitis in cattle, suggest that the inhalation of pollen may cause an allergic response of the alveolar epithelium. However, many outbreaks of the disease have occurred in cattle solely on grass pasture with no flowers; intradermal tests of sensitivity to many pasture plants and to the ruminal contents of affected animals have been negative, and blood histamine levels are within the normal range.

Mycotoxicosis and plant poisonings

In North America, the ingestion of sweet potatoes infested with the mold *Fusarium solani* has been incriminated as a cause of acute interstitial pneumonia in cattle. Growth of the mold on the potatoes produces the toxins ipomeamarone and ipomeamaronol, and a lung edema factor. The latter is a collective term for a group of substances capable of causing death associated with severe edema and a proliferative alveolitis of the lungs of laboratory animals. It produces a respiratory syndrome which is clinically and pathologically indistinguishable from ABPEE.

The fungus *Fusarium semitectum* growing on moldy garden beans, *Phaseolus vulgaris*, which were discarded on pasture, was associated with acute pulmonary emphysema in cattle that consumed the beans and their vines. The fungus produces a pulmonary toxin. The pulmonary toxin, 4-ipomeanol (ipomeanol), accumulates in mold-damaged sweet potatoes and induces pulmonary edema, bronchiolar necrosis and interstitial pneumonia in many mammalian species. Outbreaks have occurred in lactating cows following ingestion of sweet potatoes damaged by *Myzus tersicae*.[2] Other *Fursarium* spp. have been found in

peanut-vine hay, which has been associated with acute respiratory distress and atypical interstitial pneumonia in adult beef cattle.[3] The population mortality rate due to respiratory disease was about 12% and the case fatality rate 77%. Clinical signs occurred within a few days to 2 months after the animals were fed the peanut-vine hay.

A weed, *Perilla frutescens*, is considered to be a cause of the disease in cattle in the US and wherever the plant is found. High morbidity and high case fatality rates are characteristic, and the plant contains a perilla ketone which can be used to produce the disease experimentally.

Turf-quality perennial ryegrass straw (*Lolium perenne*) infected with the endophyte (*Acremonium lolii*) which yields toxic substances, including lolitrem-B has been associated with atypical pneumonia in weaned beef calves.[4] However, feeding the suspect hay resulted in typical ryegrass staggers but not atypical interstitial pneumonia.

Bacterial and *Mycoplasma* spp. infections

There is no evidence that any of the common bacterial pathogens of cattle such as *Mannheimia haemolytica, Pasteurella multocida, Histophilus (Haemophilus) somni*, or *Mycoplasma* spp. are primaily associated with acute interstitial pneumonia. In a series of feedlot cattle with clinical findings consistent with acute interstitial pneumonia, the pathogens were present in the lung tissues of some animals at necropsy but their presence was not considered as a primary cause of the pneumonia but rather secondary to the initial injury of the lung which was undetermined.[5]

Viral infections

Certain viral infections of the lung may result in interstitial pneumonia. In the interstitial pneumonias caused by the bovine respiratory syncytial virus (BRSV) there is a bronchiolitis and alveolitis and these should be termed bronchiointerstitial pneumonias. The BRSV is an important cause of outbreaks of acute interstitial pneumonia in beef calves 2–4 weeks after weaning. Pathologic evaluation of the lung tissues of feedlot cattle which had acute interstitial pneumonia found that BRSV was not a causative agent.[6] In a series of cases of interstitial pneumonia in feedlot cattle in Saskatchewan the presence of the BRSV antigen was demonstrated in only 7% of cases and there was more severe bronchiolar epithelial necrosis than in the other cases which were negative for the virus.[7]

EPIDEMIOLOGY

Acute pulmonary emphysema and edema (ABPEE) or fog fever occurs almost exclusively in adult cows and bulls, usually 4–10 days after they are moved abruptly from a dry or overgrazed summer pasture to a lush autumn pasture. The new pasture may or may not have been grazed during that summer and the species of grass or plants does not seem to make a difference, but usually there is some lush regrowth of grass, legume or other palatable plants. Merely changing pasture fields in the autumn has precipitated the disease. In the mountainous areas of North America the disease occurs commonly in cattle brought down from high altitude grasslands to the cultivated and perhaps irrigated lush pastures.

ABPEE usually occurs in outbreaks, the morbidity ranging from 10% in some herds up to 50% and higher in others, with a case fatality ranging from 25 to 50%. It is not unusual to observe a mild form of the disease in about one-third of the adults at risk but only 10% of those at risk may be severely affected. Often, a number of cows are found dead without premonitory signs; many others are severely ill and die within 24 hours and the owner believes that the entire herd will die because of the sudden onset and the large number of animals which are affected at once. Calves and young growing cattle up to 1 year of age grazing the same pasture are usually unaffected.

A retrospective analysis and random sample survey of cattle ranches in northern California found that the type of forage management has a significant effect on the occurrence of the disease. The greatest occurrence of the disease was in herds where the cattle were moved from summer ranges to second-growth hay fields or to irrigated pastures, or from one irrigated field to another. The adult morbidity rate was 2.6% and the case fatality rate about 55%. The disease did not occur on ranches with limited or no movement of cattle from summer ranges to lush autumn pastures.

Placing cattle on rape or kale forage fields or in fields where turnips have been pulled and the cattle allowed access to the tops may have the same effect. The disease has also occurred commonly in western Canada when cattle have been placed in a stubble field following harvesting of any of the cereal crops. Veterinarians have noted that the timespan over which the disease occurs during the autumn months is only 2–4 weeks and that, following the first frost in the fall, the incidence of the disease declines rapidly. The disease has also occurred in the same herd on the same pasture in successive years.

ABPEE in adult cattle in autumn has been recorded in Canada and the US, Great Britain, Holland, and New Zealand. The disease is rare in Australia. The chronic form of the disease in housed cattle appears to be the predominant form of the disease in Switzerland, but the acute form in cattle which have been changed from a dry to lush pasture is now reported. The disease has been recognized in France for many years as aftermath disease or aftermath emphysema, especially in the Normandy region. Some reports have suggested a breed incidence, Herefords being more commonly affected than the Jersey, Holstein, Shorthorn, and Angus breeds, but there are few exact epidemiological data to support the observation. One report suggested that the chronic type in housed cattle was more common in the Channel Island breeds.

Acute interstitial pneumonia in feedlot cattle. Interstitial pneumonia is recognized as important cause of economic loss in feedlot cattle in western Canada and the United States.[8] The disease occurs sporadically and the incidence is about 3.1% of all cattle placed in feedlots.[9] Cases occur most commonly during the summer and fall months and new cases occur in an even distribution across all stages of the finishing period. In southern Alberta, the disease is most common during hot, dry, dusty, spring and summer days, and typically affects animals expected to be ready for slaughter within 15 to 45 days. Some feedlot operators have observed that the disease is more common in cattle exposed to excessive dust from bedding.

In southern Alberta feedlots the disease occurred late in the finishing period, when animals had been on feed an average of 114 days and weighed 475 kg.[10] All confirmed cases were in heifers and plasma concentrations of 3-methylindole metabolites (adducts) were higher in heifers with interstitial pneumonia than in controls. Most of the heifers were receiving melengestrol (MGA) to suppress estrus. The BRSV antigen was not found in lung tissue of confirmed cases. The odds of an animal with acute interstitial pneumonia being a heifer were 3.1 times greater than the odds that an animal with the disease was a steer.[9] In some large feedlots the estimated relative risk was 4.9.

The role of 3-methylindole (3MI) has been examined as a possible cause of interstitial pneumonia in feedlot cattle.[10] Anaerobic ruminal fermentation of large amounts of tryptophan leads to a surge in 3-methylindole concentrations, which is readily absorbed across the ruminal and intestinal wall and disseminated throught the body. Bioactivation of 3MI by Clara cells leads to profound cellular injury in Clara and type-1 alveolar epithelial cells and, ultimately, acute interstitial pneumonia. It is postulated that the compound

responsible for causing the injury is the electrophilic metabolite of 3MI, 3-methylenedolenine (3MEIN) which forms stable adducts with cellular macromolecules. (Adducts are compounds formed by an addition reaction.)

Concentrations of 3-methyleneindolenine (3MEIN) in lung tissue and blood were higher in feedlot cattle that had died of acute interstitial pneumonia than in healthy feedlot cattle.[9] However, lung tissue concentrations of 3MEIN were similar in samples from cattle with interstitial pneumonia and bronchopneumonia.[9] Time-dependent patterns and magnitudes of plasma concentrations of 3MI and blood concentrations of 3MEIN-adduct in feedlot cattle during the first 8 weeks after arrival have been followed.[11] Mean concentration of 3MEIN-adduct increased to a maximum value on day 33 and then decreased to a minimum on day 54. Plasma 3MI concentrations initially decreased and remained low until after day 54. Neither 3MEIN-adduct concentrations nor plasma 3MI concentrations were associated with deleterious effects on weight gains. A single dose of acetylsalicylic acid (aspirin) to feedlot cattle on arrival did not affect serum or rumen concentrations of 3MI.[12] The combination of aspirin and vitamin E fed daily to feedlot cattle did not decrease the risk of developing respiratory tract disease.[13]

Sheep. Acute interstitial pneumonia has been recorded in sheep and there was extensive alveolar epithelialization. In Norway, an acute respiratory distress syndrome has occurred in lambs moved from mountain pastures onto lush aftermath pasture. The lesions were those of acute interstitial pneumonia and alveolar epithelial hypersensitivity to molds in the grass is being explored. The experimental oral administration of 3-methylindole to lambs will result in acute dyspnea and lesions similar to those which occur in cattle and adult sheep following dosing with 3-methylindole. However, the lesions in experimental lambs are different from those which occur in lambs affected with the naturally occurring disease.

The other types of interstitial pneumonia occur sporadically and may affect only a single animal or several over a period of time. There is not necessarily a seasonal incidence except in areas where cattle are housed and fed dusty and moldy hay during the winter months. The disease has occurred in feedlot cattle in open feedlots and in young cattle fed on fattening rations indoors.[6] Acute interstitial pneumonia occurs in weaned beef calves about 4 weeks after weaning. The interstitial pneumonia which may be the result of anaphylaxis also occurs sporadically and therefore not in outbreaks.

PATHOGENESIS

Because of the number and variety of circumstances in which acute or chronic interstitial pneumonia occurs, it is difficult to suggest a basic underlying cause, or to explain the mechanisms for the development of the lesions and the variations which occur from one circumstance to another. The reaction which occurs is a non-specific but fundamental reaction of the pulmonary parenchyma to a wide variety of insults which may be ingested, inhaled or produced endogenously. The reaction to sublethal injury is a combination of congestion, edema, an outpouring of protein-rich fluid into the alveolus, hyaline membrane formation, alveolar and interstitial emphysema which is secondary, and proliferation of alveolar septal cells and fibrosis of the interstitial spaces. Unlike the bacterial pneumonias, the emphasis is on edema and proliferation rather than on necrosis. Because mild cases of ABPEE may recover completely, it is suggested that the lesion can be reversible.

Experimental ABPEE

There has been considerable effort to experimentally induce ABPEE similar to the naturally occurring disease, by the oral administration of D,L-tryptophan or one of its metabolites, 3-methylindole, to cattle, sheep, and goats. The L-isomer of tryptophan is metabolized by ruminal microorganisms to indolacetic acid which is then converted to 3-methylindole. The conversion of L-tryptophan to 3-methylindole is maximal at a ruminal pH near neutrality. When cattle are moved from a relatively dry pasture to a lush green pasture, there is an increase in ruminal ammonia, a decrease in ruminal pH, and a decrease in ruminal buffering capacity. The 3-methylindole is absorbed from the rumen and metabolized by a mixed-function oxidase system to an active intermediate which has pneumotoxic properties.

Pulmonary edema is the first morphological change occurring in ruminants given 3-methylindole, and the severity and extent of the lesion is probably the single most important factor which determines the severity of the clinical response and the likelihood of survival. The edema is preceded by degeneration, necrosis, and exfoliation of type I alveolar septal cells. During the acute phase, there is flooding of the alveoli with serofibrinous exudate, congestion, and edema of alveolar walls, and hyaline membrane formation. Varying degrees of severity of interstitial emphysema also occur. The interstitial emphysema may spread within the lymphatics to the mediastinum and into the subcutaneous tissues over the withers, over the entire dorsum of the back and, occasionally, over the entire body including the legs. If the acute phase is severe enough there is marked respiratory distress and rapid death from hypoxemia.

In the experimental disease, the typical clinical signs of respiratory disease appear within 24–36 hours after the oral administration of L-tryptophan to adult cattle and within 4 days 50% of the dosed cows will die. The predominant pulmonary lesions include edema, interstitial emphysema, hyaline membranes, and hyperplasia of alveolar lining cells. The L-tryptophan is converted to indolacetic acid, which is decarboxylated to 3-methylindole, which is absorbed and metabolized by a mixed function oxidase system in the lung to produce pneumotoxicity.

The lesions have also been produced in cattle, sheep, and goats following oral or IV administration of 3-methylindole. Calves may be more resistant to experimental toxicity with 3-methylindole than adults, which supports the observation that the naturally occurring disease is uncommon in calves grazing the same pasture in which adults are affected. Young calves, 30–45 days of age, are susceptible to pulmonary injury induced by 3-methylindole characterized by pulmonary edema and damage to type-1 alveolar epithelial cells and non-ciliated bronchiolar epithelial cells. The 3-methylindole injury does not make the bovine lung more susceptible to the bovine respiratory syncytial virus as is the case for the parainfluenza-3 virus.

Proliferative stage. If the animal survives the acute phase, proliferation of alveolar type II cells marks the beginning of the shift from the exudative to the proliferative stages of pneumonia. There is alveolar epithelialization and interstitial fibrosis, the latter being progressive and irreversible. The central features of chronic interstitial pneumonia are intra-alveolar accumulation of mononuclear cells, proliferation and persistence of alveolar type 2 cells, and interstitial thickening by accumulation of lymphoid cells and fibrous tissue. Diffuse fibrosing alveolitis is a form of chronic interstitial pneumonia of uncertain etiology, but possibly the chronic form of ABPEE. Repeated oral administration of 3-methylindole in cattle provides a good experimental model for diffuse pulmonary fibrosis.

Effects of 3-methylindole on pulmonary function

The effects of 3-methylindole on pulmonary function and gas exchange have been examined in cattle, goats, and horses. In cattle there is impairment of sympathetic pulmonary vasconstriction, and changes in intra-acinar pulmonary arteries which may be related to a sudden elevation in arterial

and venous pressures in the pulmonary system. There are large increases in respiratory rate, minute viscous work, PCO_2 and large decreases in tidal volume dynamic lung compliance, and PO_2. All of these are compatible with the severe pulmonary edema and alveolar injury.

In goats there is a pronounced decrease in lung compliance, a moderate increase in airway resistance, a concomitant hypoxemia, a progressive decrease in tidal volume and alveolar ventilation and an increase in the dead-space-to-tidal volume ratio. These changes are characteristic of a restrictive type of respiratory tract disease in goats in which pulmonary edema and the pulmonary function changes are similar to those of adult respiratory distress syndrome in man.

CLINICAL FINDINGS

Acute bovine pulmonary emphysema and edema

This disease, also known as '**fog fever**', is usually obvious, because of its characteristic clinical presentation. The onset is sudden. Within 4–10 days after adult cattle have been moved onto a new pasture, they may be found dead without any premonitory signs. Many cattle exhibit labored breathing, often with an expiratory grunt, open-mouthed breathing, frothing at the mouth, and anxiety. Severely affected cattle do not graze, stand apart from the herd, and are reluctant to walk. If forced to walk they may fall and die within a few minutes. Often, removal of the affected herd from the pasture will result in an increased number of deaths. Moderately affected cattle continue to graze but their respirations are increased above normal. Coughing is infrequent regardless of the severity. The temperature is normal to slightly elevated (38.5–39.5°C, 102–103°F) but may be up to 41–42°C (106–108°F) during very warm weather. There is a similar variation in the heart rate (80–120/min) and those with a rate of more than 120/min are usually in the terminal stages of the disease. Bloat and ruminal atony are common in severe cases. Subcutaneous emphysema is common over the withers and may extend to the axillae and ventral aspects of the thorax. The nostrils are flared and the nasal discharge is normal. Diarrhea may occur but is mild and transient.

Loud, clear breath sounds audible over the ventral aspects of the lung, indicating consolidation without bronchial involvement, are the characteristic findings on auscultation in the early stages of the acute disease. The intensity of the breath sounds may be less than normal over the dorsal parts of the lung if involvement is severe, but in animals which survive for several days the loud crackles characteristic of interstitial emphysema are of diagnostic significance. Most severely affected cases will die within 2 days of onset but less severe cases will live for several days and then die from diffuse pulmonary involvement. Those which survive longer than 1 week will often have chronic emphysema and remain unthrifty. Of those moderately affected cattle which recover in a few days, some will develop congestive heart failure a few months later, due to chronic interstitial pneumonia (cor pulmonale). Calves running with their adult dams will usually not be affected.

Other interstitial pneumonias

These diseases usually occur sporadically, but several animals may be affected over a period of time. There may or may not be a history of a change of feed or the feeding of moldy or dusty feed. In many cases, a few days elapse after the appearance of signs before the owner is aware of the affected animals. The animal may have been treated with an antimicrobial for a bacterial pneumonia with little or no response. Dyspnea, increased respiratory effort sometimes with a grunt, deep coughing, a fall in milk production, an absence of toxemia, a variable temperature (38.5–40°C, 102–104°F) and a variable appetite are all common. On auscultation there are loud breath sounds over the ventral aspects of the lungs and crackles over both dorsal and ventral aspects. The presence of moist crackles suggests secondary bacterial bronchopneumonia. Subcutaneous emphysema is uncommon in these and most will become progressively worse.

Yearling cattle with acute interstitial pneumonia which may be viral in origin may become much worse and die in a few days in spite of therapy. Mature cattle affected with bovine farmers' lung will survive in an unthrifty state with the chronic disease for several weeks and even months.

The major clinical features of all these other interstitial pneumonias are obvious respiratory disease, lack of toxemia, poor response to treatment, progressive worsening, and abnormal lung sounds distributed over the entire lung fields.

CLINICAL PATHOLOGY

There are no abnormalities of the hemogram or serum biochemistry which have any diagnostic significance. Examination of feces and forage for lungworm larvae will aid in differentiation from verminous pneumonia if past the prepatent period. The observed high levels of 'farmer's lung hay' antibodies in serum are not of much value diagnostically because of the similar levels found in many clinically normal cows; many cases of classic fog fever have negative serum precipitin levels.

NECROPSY FINDINGS

In ABPEE, the lungs are enlarged and firm and do not collapse on cutting. In the early stages of acute cases they contain much fluid which is more viscid than usual edema fluid. The pleura is pale and opaque and appears to be thickened. In peracute cases, the entire lungs are homogeneously affected in this way. Such cases usually have edema of the larynx.

In the more common acute case, the lung has a marbled appearance. Adjacent lobes may be affected with any one of four abnormalities. Areas of normal, pink lung are restricted to the dorsal part of the caudal lobes. There are areas of pale tissue indicative of alveolar emphysema, areas of a dark pink color affected by early alveolar exudation, yellow areas in which the alveoli are filled with coagulated protein-rich fluid, and dark red areas where epithelialization has occurred. The latter two lesions are firm on palpation and resemble thymus or pancreas. They are more common in the ventral parts of the cranial lobes.

In chronic cases, as a sequel to the acute form described above, the obvious differences in the age of the lesions suggest that the disease progresses in steps by the periodic involvement of fresh areas of tissue. In all cases there is usually a frothy exudate, sometimes containing flecks of pus, in the bronchi and trachea, and the mucosa of these passages is markedly hyperemic.

Histologically, the characteristic findings are an absence of inflammation, except in the case of secondary bacterial invasion, and the presence of an eosinophilic, protein-rich fluid which coagulates in the alveoli, or may subsequently be compressed into a hyaline membrane. This is more apparent in acute cases and, if animals live for a few days, there is evidence of epithelialization of the alveolar walls. In longstanding cases, there is extensive epithelialization and fibrosis.

The pathology of bovine farmer's lung and diffuse fibrosing alveolitis has been described and consists of variations of the lesions of chronic interstitial pneumonia.

Bacteriological examination of the lungs is often negative, although in long-standing cases in which secondary bacterial pneumonia has developed *Pasteurella multocida, Mann. haemolytica, Streptococcus* spp., and *Arcanobacterium* pyogenes may be found. A careful search should be made for nematode larvae.

TREATMENT

The treatment of fog fever in cattle is empirical and symptomatic. The lesion is irreversible in severe cases and treatment is unlikely to be effective. When outbreaks of the disease occur on pasture the first reaction is to remove the entire herd from the pasture to avoid the development of new cases. However, almost all new cases will usually occur by the 4th day after the onset of the outbreak and removal from

DIFFERENTIAL DIAGNOSIS

Acute bovine pulmonary emphysema and edema

Acute bovine pulmonary emphysema and edema is usually obvious when presented with an outbreak of acute respiratory disease in adult cattle which have recently been moved onto a new pasture. The onset is sudden, many cattle are found dead and many are dyspneic. ABPEE must be differentiated from:

Pneumonic pasteurellosis

Pneumonic pasteurellosis is characterized by fever, toxemia, mucopurulent nasal discharge and less dyspnea; young cattle are more commonly affected and there is a beneficial response to therapy within 24 hours.

Organophosphatic insecticide poisoning

Organophosphatic insecticide poisoning may resemble the pasture form of pulmonary emphysema because of the dyspnea but additionally there is pupillary constriction, mucoid diarrhea, muscular tremor and stiffness of the limbs, and no abnormal lung sounds.

Nitrate poisoning

Nitrate poisoning may occur in cows moved into a new pasture with high levels of nitrate. Many cows are affected quickly, they are weak, stagger, gasp, fall down, and die rapidly. The chocolate brown coloration of the mucous membranes, the lack of abnormal lung sounds, and the response to treatment are more common in nitrate poisoning.

Other interstitial pneumonias

All of the other types of acute interstitial pneumonia in cattle not associated with a change of pasture in the autumn are difficult to diagnose clinically and pathologically, especially when they occur in a single animal. Their epidemiological characteristics summarized on p. 513 will often offer some clues.

The chronic and subacute types of interstitial pneumonia are difficult to differentiate from each other and from other pneumonias of cattle.

Bovine farmer's lung

Bovine farmer's lung or extrinsic allergic alveolitis occurs in housed cattle exposed to dusty or moldy feeds for a prolonged period and is characterized by a history of chronic coughing, weight loss, poor milk production, occasionally green-colored nasal discharge, and dry crackles over most aspects of the lungs. Not infrequently, acute cases occur and die within a week after the onset of signs.

Lungworm pneumonia

Lungworm pneumonia occurs in young cattle on pasture in the autumn months and causes subacute or acute disease which may resemble bovine farmer's lung clinically but not epidemiologically. Necropsy is necessary for the diagnosis.

Verminous pneumonia

Verminous pneumonia caused by aberrant migration of *Ascaris suis* larvae may be indistinguishable from acute interstitial pneumonia, but a history of previous occupation of the area by pigs may provide the clue to the diagnosis which can only be confirmed on histological examination of tissues. It is impossible to differentiate clinically between verminous pneumonia and some of the acute interstitial pneumonias seen in yearling cattle except by identification of the larvae in the feces or tissues of affected animals.

Feedlot interstitial pneumonia

Feedlot interstitial pneumonia occurring in recently weaned beef calves or feedlot cattle is characterized by the sudden onset of acute respiratory distress, absence of toxemia, lack of abnormal nasal discharge, and a poor response to treatment with antibiotics. It is difficult to differentiate clinically from acute viral interstitial pneumonia or pneumonic pasteurellosis. However, in acute interstitial pneumonia there is marked dyspnea and the abnormal lung sounds are usually distributed over the entire lung fields.

Enzootic pneumonia of calves

Enzootic pneumonia of calves may resemble acute or chronic interstitial pneumonia but is almost entirely restricted to housed calves less than 6 months of age. They respond to treatment gradually over a few days.

the pasture usually will not prevent new cases. Conversely, leaving the herd on pasture usually will not result in additional cases. Severely affected cattle should be removed from the pasture with extreme care, very slowly and only if necessary, and moved to shelter from the sun. Immediate slaughter for salvage may be indicated in severe cases. Mild or moderately affected cases will commonly recover spontaneously without any treatment if left alone and not stressed, a fact that has not been given due consideration when claims are made for the use of certain drugs.

Several different drugs have been advocated and used routinely for the treatment of ABPEE in cattle. However, none has been properly evaluated and definitive recommendations cannot be made.

Treatment of the chronic interstitial pneumonias is unsatisfactory because the lesion is progressive and irreversible.

CONTROL

There are no known reliable methods for the prevention of ABPEE in pastured cattle but there are some strategies which merit consideration.

Grazing management

If lush autumn pasture contains toxic levels of the substance that causes the acute disease it would seem rational to control the introduction of cattle to the new pasture. This can be done by controlling the total grazing time during the first 10 days: allow the cattle to graze for 2 hours on the first day, increasing by increments of 1 hour per day, and leave them on full time at the end of 10–12 days. Such a management procedure is laborious, requires supplementation with other feeds and daily removal of cattle from the pasture, and may not be practical depending on the size and terrain of the pasture and the holding yards which are available.

Inhibition of 3-methylindole production in rumen

Controlling the conversion of D,L-tryptophan in forage to 3-methylindole is a plausible control strategy. Experimental tryptophan-induced ABPEE can be prevented by the simultaneous oral administration of chlortetracycline or polyether antibiotics such as monensin. The daily oral administration of 2.5 g/head of chlortetracycline beginning 1 day before and for 4 days following administration of a toxin of L-tryptophan will prevent clinical signs.[14]

The daily oral administration of monensin at the rate of 200 mg/head/day beginning 1 day before and for 7 days after an abrupt change from a poor quality hay diet to a lush pasture reduced the formation of 3-methylindole during the 7 days of treatment, but the effect of the drug was dimished on day 10, 3 days after its withdrawal. Because the effects of monensin on ruminal 3-methylindole are diminished within 48 hours after withdrawal of the drug, effective prevention of acute pulmonary edema and emphysema may require continuous administration of monensin for the critical period of approximately 10 days after the mature animals are exposed to the lush pasture. The daily feeding of monensin in either an energy or protein supplement will effectively reduce ruminal 3-methylindole formation in pasture-fed cattle.

Successful prevention of the disease requires monensin supplementation with organized grazing management to reduce the intake of lush pasture by hungry cows. This may be accomplished in several ways: feed dry, mature hay ad libitum to adult cattle just before and during the transition period of a pasture change, then continue to feed hay for at least 4 days into this grazing period; cut all lush forage and allow to wilt before allowing adult cattle access to the

pasture. Alternatively, over a 7-day period, gradually increase the amount of time cattle spend grazing lush pasture. If possible, this may be accomplished by rotating cattle back and forth, either between the summer and fall pastures, or between the fall pasture and a drylot where ample supply of dry, mature hay is available. Any combination of these management practices while providing monensin at 200 mg/head per day in an energy or protein supplement may reduce 3-methylindole production to a greater extent than just providing monensin or implementing grazing management techniques.[6]

To maximize the effectiveness of monensin in reducing 3-methylindole formation, dry hay plus wilted forage should be fed to pastured cattle for at least 4 days after they are allowed access to lush pasture. Lasalocid at a dose of 200 mg per head once daily in ground grain for 12 days reduced the conversion of tryptophan to 3-methylindole and prevented pulmonary edema.[15]

The daily administration of inhibitors during the critical period immediately before and after the cattle are turned onto the lush pasture may be a practical problem.

Other interstitial pneumonias

The control of non-pasture cases of interstitial pneumonia depends on the suspected cause and removal of it from the environment of the animals. Every attempt must be made to control the concentration of dust and moldy foods to which cattle are exposed. Feed supplies must be harvested, handled, and stored with attention to minimizing dust and molds. In the preparation of mixed ground feed for cattle, the fineness of grind must be controlled to avoid dusty feed particles which may be inhaled. Because of the creation of dust, the grinding and mixing of dry feeds like hay, straw, and grains should not be done in the same enclosed area in which cattle are housed. If dusty feeds must be used they should be wetted to assist in dust control.

Lungworm control is essential in endemic areas where the disease occurs. This may necessitate careful monitoring and regular treatment to reduce the level of infestation on pasture.

Viral interstitial pneumonias. In countries where cattle are housed, especially during the winter months, the provision of adequate ventilation is necessary to minimize aerosol viral interstitial pneumonias. Vaccination is a consideration.

TRACHEAL STENOSIS OF FEEDLOT CATTLE

Tracheal stenosis, also known as 'honker cattle', occurs in feedlot cattle.[1] The etiology is unknown. It is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premonitory signs.

In tracheal stenosis of feedlot cattle, there is marked submucosal hemorrhage dorsal and ventral to the tracheal is muscle resulting in ventral displacement of the mucosa and partial to complete occlusion of the tracheal lumen. Diffuse hemorrhage in the peritracheal connective tissue and surrounding muscles of the neck is common in animals dying of asphyxia. Histologically there is hyperemia and hyperplastic tracheal mucosa with focal erosions, squamous metaplasia, and loss of cilia. In acute cases the mucosa is markedly thickened because of hemorrhage and edema. Culture reveals a mixed bacterial flora.

INTERSTITIAL PNEUMONIA OF ADULT HORSES

In its most severe form, this is a disease characterized by insidious progression of pulmonary inflammation and fibrosis. Less severe forms, associated with transient viral or bacterial infections of the lungs, resolve when the infection is cleared from the lungs.

ETIOLOGY

There are many potential agents but few have been conclusively implicated as being associated with the disease. In most instances of the disease no causal association is identified.

Interstitial pneumonia is a common finding in horses associated with various infectious agents (Hendra virus infection, *Rhodococcus equi* in foals, *Aspergillus* sp., *Cryptococcus* sp. and *Hisptoplasma* sp., *Pnemoncystis carinii*,[1] *Parascaris equorum*, and *Dictyocaulus arnfiedli*). Intoxication with perilla ketone, derived from Perilla frutescens, causes acute restrictive lung disease of horses.[2,3] Similary, ingestion of *Eupratorium* sp. in Australia and Hawaii causes interstitial pneumonia in horses.[4] Inhalation of silica causes a similar disease in horses in California.[5] Inhalation or ingestion of agricultural chemical or environmental toxins (e.g. paraquat) has the potential to cause interstitial pneumonia in other species, but this has not been demonstrated in horses.

Hypersensitivity reactions may cause severe respiratory disease in horses. Incriminating allergens include fungi (unspecified) and chicken dust.[6,7]

Interstitial pneumonia has also been reported subsequent to administration of an immunostimulant containing mycobacterial cell wall extract.[8]

EPIDEMIOLOGY

The disease occurs in adult horses without apparent breed, sex, or age predisposition. In cases in which the cause is infectious, the epidemiology of the disease is characteristic of that of the causal organism.

PATHOGENESIS

The initial insult causes injury to parenchymal cells and an acute alveolitis.[9] Alveolitis results from damage to epithelial and endothelial cells by toxic, metabolic (free radicals), or infectious agents. This is followed by a phase of cellular proliferation of type 2 pneumocytes and fibroblasts with connective tissue deposition.[3] At this time there is an influx of inflammatory cells, the exact type depending to some extent on the cause of the disease. Infiltration of neutrophils, lymphocytes, and macrophages is common. Continued injury to the lung results in development of severe interstitial fibrosis and destruction of gas exchange units.

Interstitial pneumonia results in altered pulmonary function including reduced compliance, impaired pulmonary gas exchange, and a reduction in total and vital lung capacity. The work of breathing is increased.[10]

CLINICAL SIGNS

Horses with idiopathic interstitial pneumonia have various combinations of: weight loss, recurrent cough, depression,

anorexia, fever, or respiratory distress. Signs of respiratory disease are not readily apparent at initial examination in all affected horses. As the disease progresses respiratory distress develops in most, but not all, cases. The usual history of is a gradual onset of increased respiratory effort, although some horses have a sudden onset of respiratory distress.[11] Heart and respiratory rates may be elevated. Pyrexia is not a constant finding. There may be a nasal discharge. Thoracic auscultation may reveal only increased intensity of normal breath sounds or the presence of occasional crackles and wheezes. Typically, there is tachypnea with an increased respiratory effort.

Thoracic radiography reveals pulmonary disease, usually apparent as severe, diffuse interstitial disease. The interstitial opacity may be diffuse or nodular with multiple well defined opacities against an overall background of increased interstitial density. Ultrasonographic examination may reveal the presence of multiple nodules in the lung parenchyma confluent with the pleural surface. There is no excess pleural fluid.

Intradermal skin testing may be useful to identify the inciting allergen in cases of allergic interstitial pneumonia.[7]

The prognosis is poor in most cases of the idiopathic disease. Should recovery occur, it does so within approximately 2 weeks of diagnosis.

CLINICAL PATHOLOGY

Hematologic examination usually reveals a neutrophilic leukocytosis.[11,12] Mild anemia and hyperfibrinogenemia are common. Examination of a tracheal aspirate reveals neutrophil inflammation. In cases of verminous pneumonia, there may be an increased proportion of eosinophils in tracheal aspirate. Bronchoalveolar lavage fluid can reveal a similar neutrophilic leukocytosis or may be normal.[13] Serologic testing for antibodies to fungi or other inciting agents may be useful.[9]

Definitive diagnosis is provided by examination of tissue obtained by lung biopsy.

NECROPSY FINDINGS

The lungs do not deflate as anticipated and there may be indentations from the ribs on the surface of the lungs. Multiple pale, yellowish-white nodules 3–4 cm in diameter may be apparent on the surface of the lung and throughout the lung parenchyma. There is histologic evidence of severe, fibrosing alveolitis with minimal airway involvement. The acute phase of the disease is evident as extensive alveolar edema and hemorrhage.[14]

TREATMENT

Treatment should be directed toward any cause of the disease that is identified such as administration of anthelmintics. In cases of idiopathic disease, treatment is frequently unrewarding as by the time the animal is examined the disease is often advanced. Treatment includes anti-inflammatory drugs including dexamethasone or prednisolone, antimicrobials, and supportive care. Immunosuppressive drugs, such as vincristine, are not effective. Bronchodilating drugs, such as clenbuterol, may be considered, but bronchoconstriction is not a prominent component of the disease.

CONTROL

Prevention of exposure to potential infectious, toxic or environmental causes is prudent.

ACUTE BRONCHO-INTERSTITIAL PNEUMONIA IN FOALS

This is a disease of foals less than 7 months of age, and usually <2 months of age, characterized by a rapid onset of respiratory distress. The **etiology** is unclear in many cases, but suggested causes or agents associated with the disease include equine influenza virus infection,[1] *R. equi*, equine herpes virus II, equine arteritis virus,[2] or *Pneumocystis carinii*.[3–6] The disease is likely a result of severe pulmonary injury by any of a number of infectious or toxic agents. The respiratory distress results from loss of pulmonary function because of necrosis of the epithelium of alveoli and terminal bronchioles.

Foals typically present with an acute onset (<4 days) of respiratory distress, pyrexia and tachycardia. Foals are depressed and reluctant to eat. There is a pronounced respiratory effort with a marked abdominal component in most affected foals. Crackles, wheezes, and increased bronchial breath sounds are auscultable in most foals. Radiographic examination reveals a bronch-interstitial pattern which is always diffuse, although in some foals there is also a focal interstitial pattern. The prognosis is guarded, with approximately 50% of affected foals dying of the disease.

There is a neutrophilic leukocytosis and hyperfibrinogenemia in most cases. Arterial hypoxemia is present in severely affected foals. Tracheal aspirate demonstrates neutrophilic inflammation. Culture of the tracheal aspirate yields *Rhodococcus equi*, *Strep. zooepidemicus*, *Actinobacillus* sp., and other organisms of questionable significance. Serology might demonstrate evidence of infection by equine influenza virus or equine herpes virus II.[1,3,4] Viral isolation can identify equine influenza virus.[1]

NECROPSY FINDINGS

Necropsy examination reveals the presence of diffusely reddened, wet and firm lungs that fail to collapse.[3,4] The predominant histologic lesion is necrosis of the epithelium of terminal bronchioles and alveoli.

TREATMENT

Principles of **treatment** are correction of hypoxemia, reduction of inflammation and removal of inciting causes. Severely affected foals may require nasal insufflation of oxygen to ameliorate or correct hypoxemia. Administration of corticosteroids has been associated with improved survival.[3] Broad spectrum antibiotics are administered to treat concurrent bacterial infections and prevent secondary infection.

CONTROL

There are no specific control measures, but reduction of exposure of foals to infectious respiratory disease would be prudent.

CHRONIC INTERSTITIAL PNEUMONIA OF FOALS

A sporadic disease of foals less than 10 months of age characterized by respiratory distress of several weeks duration is caused by chronic interstitial pneumonia.[1] The etiology is unknown, but the disease likely represents a common final response to injury caused by any one of a number of infectious or toxic agents (see 'interstitial pneumonia of horses' and 'acute bronchointerstitial pneumonia of foals').

Affected foals are bright and alert and have markedly increased respiratory effort. The respiratory rate is elevated and there is a prominent abdominal component to respiratory effort. Fever is low grade and intermittent. Thoracic auscultation reveals increased intensity of normal breath sounds and the presence of wheezes and crackles in most affected foals. Ultrasonographic examination of the thorax reveals extensive 'comet tail' signs in most cases. Radiography demonstrates the presence of moderate to severe interstitial pneumonia which in some cases can include focal opacities suggestive of alveolar disease. The prognosis with appropriate treatment is excellent.

Affected foals have neutrophilic leukocytosis and hyperfibrinogenemia. Serological examination for antibodies to common respiratory viruses is unrewarding. Culture of tracheal aspirates does not consistently yield growth of known pathogens. Lung biopsy is not warranted because the characteristic changes on radiographic examination, combined with the clinical signs, are diagnostic for the disease. The risk of adverse events associated with lung biopsy outweighs any diagnostic utility given the good prognosis for complete recovery from the disease.

Treatment consists of administration of corticosteroids such as dexamethasone phosphate at an initial dosage of 0.1–0.25 mg/kg intravenously for 3–5 days followed by a declining dose administered orally over 2–3 weeks. Prednisolone can be substituted for dexamethasone. Broad spectrum antibiotics (combination of penicillin and aminoglycoside, trimethoprim-sulfonamide, or doxycycline) should be administered for 1–2 weeks.

There are no recognized control measures, although control of infectious respiratory disease in the herd is prudent.

Diseases characterized by nervous system involvement

POLIOENCEPHALOMALACIA (CEREBROCORTICAL NECROSIS) OF RUMINANTS

Synopsis

Etiology Several different causes including thiamin inadequacy, sulfate toxicity.
Epidemiology Sporadic disease in young well-nourished ruminants on high level grain diets and not synthesizing sufficient thiamin. Ingestion of preformed thiaminase in certain plants or production by ruminal microbes may also cause destruction of thiamin. May also occur in cattle and sheep of all ages ingesting excess amount of sulfates in feed and water.
Signs Sudden blindness, ataxia, staggering, head-pressing, tremors of head and neck, ear twitching, champing fits, clonic-tonic convulsions, recumbency, opisthotonos, rumen contractions normal initially, pupils usually normal and responsive, nystagmus, death may occur in 24–48 hours. Hydrogen sulfide odor of ruminal gas in sulfate toxicity.
Clinical pathology Erythrocyte transketolase activity decreased and thiamin pyrophosphate effect increased but both measurements difficult to interpret; blood thiamin levels decreased but not reliable.
Lesions Diffuse cerebral edema, flattened dorsal gyri, coning of cerebellum, multifocal to linear areas of fluorescence in gray and white matter borders of cortical gyri and sulci.
Diagnostic confirmation Fluorescence of gray and white matter of cortical gyri and sulci of brain.

Differential diagnosis list
Cattle:

- Lead poisoning
- Hypovitaminosis-A
- *Histophilus meningoencephalitis.*

Sheep:

- Pregnancy toxemia
- Clostridium perfringens Type D Enterotoxemia
- Focal symmetrical encephalomalacia
- Lead poisoning.

Goats:

- Caprine leukoencephalomyelitis
- Listeria meningoencephalitis
- Clostridium perfringens Type D Enterotoxemia
- Lead poisoning.

Treatment Thiamin hydrochloride parenterally.
Control Thiamin supplementation of diet. Avoid excess feeding or access to sulfate in feed and water supplies.

ETIOLOGY

Historically, PEM was considered to be caused by a thiamin inadequacy. It is now known that there are several different causes of the disease.

Thiamin inadequacy

The evidence that a thiamin inadequacy can be associated with the disease includes the following[1]:

- Affected animals respond to the parenteral administration of thiamin if given within a few hours after the onset of clinical signs
- Affected animals have biochemical findings consistent with thiamin diphosphate (TDP) inadequacy
- The clinical signs and pathological lesions can be reproduced in sheep and cattle by the administration of large daily doses of pyrimidine containing structural analogs of thiamin, principally amprolium, given orally or intraperitoneally.[1]

Excess dietary sulfur

The ingestion of excessive quantities of sulfur from the diet and water supply can cause the disease in cattle[2] and sheep[3] without any change in the thiamin status of the tissues.

EPIDEMIOLOGY

Occurrence

PEM occurs sporadically in young cattle, sheep, and goats, and other ruminants. In North America, UK, Australia, and New Zealand, the disease has been most common in cattle and sheep which are being fed concentrate rations under intensified conditions such as in feedlots. An inadequate amount of roughage can result in a net decrease in the synthesis of thiamin. The disease occurs most commonly in well-nourished thrifty cattle 6–18 months of age (peak incidence 9–12 months of age) which have been in the feedlot for several weeks. Feedlot lambs may also be affected only after being on feed for several weeks. The disease also occurs in goats and in antelope and whitetail deer.[4] The disease may affect goats from 2 months to 3 years of age and is commonly associated with milk-replacer diets in kids or concentrate feeding in older goats. The disease occurs only rarely in adult cattle which may be a reflection of the greater quantities of roughage they usually consume. However, there are recent reports of the disease occurring in adult cows on pasture with access to drinking water containing excessive concentrations of sulfates.[2]

In Cuba, the disease occurred in feedlot cattle fed primarily on molasses with a minimal quantity of roughage, and was reproduced by feeding a molasses-urea and roughage diet by gradual removal of the roughage without the use of thiamin analogs.

Morbidity and case fatality

Accurate morbidity and case fatality data are not available, but outbreaks can occur suddenly in which up to 25% of groups of feeder cattle may be affected, with case fatality rates from 25 to 50%. Case fatality rates are higher in young cattle (6–9 months) than in the older age group (12–18 months) and mortality increases if treatment with thiamin is delayed for more than a few hours after the onset of signs. In feedlot lambs, it has been suggested that approximately 19% of all deaths are due to polioencephalomalacia.

Risk factors

When PEM was first described in 1956, and for about 30 years, it was considered

to be a thiamin deficiency conditioned by dietary factors such as high-level grain feeding and inadequate roughage. PEM occurred most commonly in well nourished young cattle from 6 to 12 months of age which were being fed high-level grain rations. The scientific investigations centered on the effects of dietary factors such as grain diets, and the presence of thiaminases in certain diets on thiamin metabolism in the rumen. In recent years, it has become clear that the disease is not etiologically specific because many different dietary factors have been associated with the occurrence of the disease, and in some instances the thiamin status of the affected animals is within the normal range. Notable examples are the recent observations linking dietary sulfate with the occurrence of the disease.

Dietary risk factors

While there has been general agreement that thiamin inadequacy is associated with the cause of PEM, the possible mechanisms by which this occurs are uncertain.[5] Thiamin inadequacy in ruminants could, theoretically, occur in any of the following situations where inadequate net microbial synthesis of thiamin in the rumen may occur:

- Concentrate-fed animals receiving inadequate roughage
- Impaired absorption and/or phosphorylation of thiamin
- The presence of a thiamin inhibitor in the tissues of the host
- Lack of sufficient or appropriate apoenzyme or coenzyme-apoenzyme binding for thiamin dependent systems
- Increased metabolic demands for thiamin in the absence of increased supply
- Increased rate of excretion of thiamin resulting in its net loss from the body.

Thiamin can be destroyed by thiaminases of which significant amounts can be found in the rumen contents and feces of cattle and sheep affected with naturally occurring polioencephalomalacia.

Thiamin inadequacy

In cattle under farm conditions, using transketolase activity as a measurement of thiamin status, up to 23% of cattle under 2 years of age and 5% over 2 years may be in a thiamin-low state. Newly weaned beef calves on a hay diet are not subject to a thiamin deficiency but a low and variable proportion of young cattle on barley-based feedlot diets (1.7%) may have some evidence of thiamin deficiency based on a thiamin pyrophosphate activity effect in excess of 15%.[2] The supplementation of the diet of feedlot steers on an all-concentrate barley-based diet with thiamin at 1.9 mg/kg DM resulted in an increase in average daily gain and final carcass weights. Thus some animals may be marginally deficient in thiamin which may be associated with decreased performance in cattle fed all-concentrate diets. However, thiamin supplementation of cattle on all-concentrate diets does not consistently result in improved animal performance. The experimental disease can be produced in young lambs fed a thiamin-free milk diet and it may be unnecessary to postulate that thiamin analogs produced in the rumen are essential components of the etiology.

Thiaminases

A major factor contributing to PEM in cattle and sheep is a progressive state of thiamin deficiency caused by the destruction of thiamin by bacterial thiaminases in the rumen and intestines. Certain species of thiaminase-producing bacteria have been found in the rumen and intestines of animals with PEM. *Bacillus thiaminolyticus* and *Clostridium sporogenes* produce thiaminase type I and *Bacillus aneurinolyticus* produces thiaminase type II. While there is good circumstantial evidence that the thiaminases from these bacteria are the real source of thiaminases associated with the disease, it is not entirely certain. The experimental oral inoculation of large numbers of thiaminase type I producing *Clostridium sporogenes* into lambs did not result in the disease.

Certain species of fungi from moldy feed are also thiaminase producers but the evidence that they destroy thiamin and are associated with PEM is contradictory and uncertain.

The factors which promote the colonization and growth of thiaminase-producing bacteria in the rumen are unknown. Attempts to establish the organism in the rumen of healthy calves or lambs have been unsuccessful. Thiaminases have also been found in the rumen contents and feces of normal animals which may suggest the existence of a subclinical state of thiamin deficiency.[5] Poor growth of unweaned and weaned lambs can be associated with a thiaminase-induced subclinical thiamin deficiency. Weekly testing of young lambs over a period of 10 weeks revealed that 90% of unthrifty lambs were excreting high levels of thiaminase in their feces; low levels of thiaminase activity were present in 20% of clinically normal animals, and there were significant differences in the mean erythrocyte transketolase activity of the unthrifty animals excreting thiaminase compared to the thiaminase-free normal animals.[5]

Field and laboratory investigations have supported an association between inferior growth rate of weaner sheep in Australia and a thiaminase-induced thiamin deficiency.[5] Thiaminase activity has been detected in the feces of lambs at 2–5 days of age, with the levels increasing for 10 days and then declining over the next 3–4 weeks.[5] Decreased erythrocyte transketolase activity indicated a thiamin insufficiency in lambs with high thiaminase activity and mean growth rates were 17% less than lambs with low thiaminase activity. The oral supplementation with thiamin at 2–3 weeks of age was the most appropriate prevention and treatment for subclinical thiamin deficiency.[5]

The parenteral or oral administration of thiamin to normal calves raised under farm conditions resulted in a marked reduction in the percentage thiamin pyrophosphate effect which is an indirect measurement of thiamin inadequacy. Goats with PEM were found to have elevated ruminal and fecal thiaminase activities, low erythrocyte transketolase activity, elevated thiamin pyrophosphate effect, low liver and brain thiamin levels, and elevated plasma glucose levels compared with goats not affected with the disease. With the increased interest in goat farming, some breeders attempt to improve body condition of breeding stock for sale or show by feeding grain or concentrate, which creates a situation similar to feedlot rearing of sheep and cattle which is conducive to the establishment of thiaminases in the rumen and the occurrence of polioencephalomalacia.

High levels of thiaminase type I are present in the rhizomes of bracken fern (*Pteridium aquilinum*) and horsetail (*Equisetum arvense*). The feeding of the bracken fern rhizomes (*Pteridium esculentum*) to sheep will cause acute thiamin deficiency and lesions similar to those of polioencephalomalacia but neither of these plants is normally involved in the natural disease. The disease has occurred in sheep grazing the Nardoo fern, *Marsilea drummondii*, in flood-prone or low-lying wet areas in Australia. The fern contains a high level of thiaminase type I activity.

Amaranthus blitoides (prostrate pigweed) may contain high levels of thiaminase and be associated with polioencephalomalacia in sheep.[6]

Sulfates

Polioencephalomalacia has been associated with diets high in sulfur, particularly in the form of sulfate. A high concentrate of sulfates in the diet of cattle has been associated with episodes of the disease in 6–18-month-old cattle. **Inorganic sulfate salts in the form of gypsum (calcium sulfate)** added to feedlot rations to control the total daily intake of the diet may cause PEM.[7] Seasonal outbreaks have occurred in feedlot beef cattle between 15 and 30 days after introduction to a **high-sulfur**

diet and the risk may increase when water is an important source of dietary sulfur, and during hot weather, when the ambient temperatures exceeded 32°C.[8]

Initial outbreaks may follow the use of a **new well of water containing more sulfate** than water used previously from another well, increasing from a monthly incidence of 0.07% to 0.88%. Growing cattle consume 2.4 times more water when the temperature is 32°C than at 4°C and consequently total ingestion of sulfur by consumption of high sulfate water increases during hot weather. The feed contained 2.4 g of SO_4/kg DM with a total sulfur content of 0.20%. Samples of drinking water contained between 2.2 and 2.8 g of SO_4/L. During hot weather daily sulfur ingestion from feed and water combined was estimated to be 64 g/animal corresponding to total dietary sulfur of approximately 0.67% of DM. Daily SO_4 ingestion was approximately 160 g/animal.[8] The ruminal sulfide levels were much higher 3 weeks after entering the feedlot, when the incidence of the disease was greatest, than 2 months after entering the feedlot when the risk of the disease was low.

In western Canada, there is an association between PEM and high levels of sodium sulfate in water, and range cows are usually affected when certain waters become concentrated with this salt during the summer months.[2] Water containing high levels of magnesium sulfate, often called ***'gyp water'***, is common in the western plains and intermountain areas of the United States and Canada.[9] Ideally, water for livestock consumption should contain less than 500 ppm sulfate, and 1000 ppm is considered the maximum safe level in water for cattle exposed to moderate dietary sulfur levels or high environmental temperatures. A level of 2000 ppm of sulfate in drinking water is the taste discrimination threshold for cattle. Performance of feedlot cattle is reduced when offered water with sulfate levels of 2000 ppm or higher. The National Research Council states that the requirement of sulfur in feed to be 1500 to 2000 ppm for both growing and adult beef cattle; 4000 ppm is considered the maximum tolerated dose.[9] Ruminant diets normally contain between 1500 to 2000 ppm (0.15–0.20% sulfur).

Based on National Research Council guidelines, 30 g of sulfur is the calculated maximum tolerated dose of sulfur for a 650 lb (294 kg) steer consuming 16.25 (7.39 kg; 2.5% BW) of feed daily. If the ambient temperature reaches 32°C, a 650 lb steer can drink 14.5 gallons (53.9 L) of water daily, Consumption of 14.5 gallons of water containing 3000 ppm sulfate results in a daily intake of 55 g sulfur. A feed intake of 2.5% BW would also consume 22.2 g of sulfur from feed containing 3000 ppm sulfur for a total daily intake of 77.2 g of sulfur from both feed and water which is 2.5 times the maximum tolerated dose.

In some surveys, water supplies in western Canada contained contained 8447 ppm of total dissolved solids and 5203 ppm of sulfate. A survey of the sulfate concentrations in water on farms, found that high levels of sulfate can have a detrimental effect on the thiamin status of the cattle on those farms.[10] Cattle exposed to sulfate concentrations >1000 ppm had blood thiamin levels lower than those drinking water with low levels <200 ppm. This raises the possibility that a subpopulation of cattle under such circumstances could be marginally deficient in thiamin.

The total dietary intake of sulfur by cattle must be considered when investigating sulfur as a cause of PEM. In a study of one farm, water from a 6.1 m well containing 3875 mg/L of total dissolved solids with 3285 mg/L of sodium sulfate was associated with PEM in heifers 6 months of age.[11] However, the water contributed about 20% of the total sulfur content in the diet of the heifers, and 60% of the dietary sulfur intake was supplied by the hay and 20% by the grain supplement. The hay contained 0.4% total sulfur which is at the maximum tolerable level for cattle and at the upper limit for hay.[11] The hay consisted of variable amounts of kochia (*Kochia scorpia*) and Canada thistle (*Cirsium arvense*). *Kochia scorpia* (summer cypress or Mexican fireweed), is high in sulfur content and has been associated with the disease in range cattle.

PEM has occurred in pastured cattle usually 5–10 days after change from a poor to a good pasture, and may occur in range cattle grazing on dry, short, grama grass pasture.[12]

The levels of sulfate in water which have affected feed intake in cattle have varied from 2800 to 3340 mg sulfate per/L while other studies found no reduction in feed intake with levels up to 7000 mg/L.[11] It appears that the different effects of sulfur toxicity for similar sulfur contents in saline water are attributed to the total sulfur intake. Outbreaks of the disease may occur in adult cattle on pasture drinking water containing 7200 ppm of sodium sulfate.[2] Thus established guidelines for saline drinking water are not applicable when cattle are fed feeds grown in saline areas.

A combination of excessive intake of sulfur and a low dietary intake of trace minerals, especially copper, may affect the thiamin status of a cattle herd and contribute to PEM.[13] Sulfur adversely affects both thiamin and copper status in sheep.[14] A nutritionally related PEM has also been reproduced in calves fed a semipurified, low-roughage diet of variable copper and molybdenum concentrations and it was not related to copper deficiency.[15] The disease has occurred in cattle in New Zealand fed chou moellier (*Brassica oleracea*) which contained sulfur concentrations of 8500 mg/kg DM.[16] The morbidity was 25% and mortality 46% despite rapid conventional therapy.

Ammonium sulfate used as a urinary acidifier in the rations of cattle and sheep has been associated with outbreaks of PEM.[3] Morbidity rates ranged from 16 to 48% and mortality rates from 0 to 8%. Affected animals did not respond to treatment with thiamin.

Outbreaks have occurred in sheep exposed to an alfalfa field previously sprayed with 35% **suspension of elemental sulfur**.[17] The disease can be induced experimentally in lambs by the administration of sodium hydrosulfide into the esophagus[18] and has occurred in lambs 3–4 weeks after being fed a concentrate ration containing 0.43% sulfur.[19] Feeding experimental diets containing inorganic sulfur to young lambs was associated with PEM and supplementation of those diets with thiamin decreased the severity of the lesions.[20] Rumen microbes are able to reduce sulfate to sulfides which may be directly toxic to the nervous system. Feeding calves (115–180 kg) a semipurified diet high in readily fermentable carbohydrate, without long fiber, and with added sodium sulfate for a total sulfur content of 0.36% resulted in PEM within 21 days of the introduction of the experimental diet.[21] An odor of hydrogen sulfide was frequently detected upon passage of a stomach tube into the rumen of all calves during the experiment. The total thiamin concentrations in affected and control calves remained within normal limits.

The dietary content of copper, zinc, iron, and molybdenum may also have important modifying influences on sulfur toxicosis. Molybdenum and copper can combine with sulfur to form insoluble copper-thiomolybdate. Copper, zinc, and iron form insoluble salts with sulfide, and their expected effect would be to decrease the bioavailability of sulfide in the rumen. Conversely, low, but not necessarily deficient, dietary contents of these divalent metals could be prerequisites for excess absorption of sulfide to occur. PEM is not associated with copper deficiency but copper and sulfur metabolism are interdependent. An excess of dietary sulfur may result in depression of serum copper, or alternatively, low serum copper may potentiate the actions of toxic levels of sulfur. Chronic copper poisoning in a lamb has been associated with PEM.[22] It is suggested that the copper toxicity may have caused decreased hepatic function resulting in

increased plasma concentration of sulfur containing amino acids which may have predisposed to sulfur toxicity encephalomalacia.

Molasses toxicity occurs in Cuba in cattle fed on a liquid molasses-urea feeding system with limited forage. The clinical and necropsy findings are identical to polioencephalomalacia. However, molasses toxicity is not thiamin responsive and can be reversed by feeding forage. Molasses has high inorganic sulfur content and the thiamin concentrations in the brain and liver with PEM which were fed molasses and urea did not differ from those in normal cattle.

Other dietary circumstances

Deprivation of feed and water. In some outbreaks there is a history of deprivation of feed and water for 24–28 hours, because of either a managerial error or frozen water supplies. In other cases, a rapid change in diet appears to precipitate an outbreak. Some outbreaks are associated with a temporary deprivation of water for 24–36 hours, followed by sudden access to water and an excessive supply of salt, a situation analogous to salt poisoning in pigs, but these require more documentation to insure that they indeed are not salt poisoning.

In sheep flocks, a drastic change in management, such as occurs at shearing time, will precipitate outbreaks in which only the yearlings are affected. Changing the diet of sheep from hay to corn silage resulted in a decrease in thiamin concentrations in ruminal fluid to about 25% of control values on hay. The cause of the drop in thiamin concentrations is unknown.

Phalaris aquatica 'polioencephalomalacia-like' sudden death in sheep and cattle. The Mediterranean perennial grass, *Phalaris aquatica* (formerly *Phalaris tuberosa*) can cause sudden death in sheep and cattle throughout southern Australia.[23] The nervous form of disease is similar clinically to polioencephalomalacia but atypical because of the very rapid onset and the absence of either neuronal necrosis or malacia in cerebral cortical sections from affected animals. The available evidence suggests that this form of phalaris sudden death is more likely to involve a peracute form of ammonia toxicity than a peracute form of polioencephalomalacia.

PATHOGENESIS

Thiamin inadequacy polioencephalomalacia

High levels of thiaminases are formed in the rumen, which destroy thiamin that is naturally synthesized.[1] The circumstances in the diet or in the rumen which allow for the development of high levels of thiaminases are unknown but may be related to the nature of the ruminal microflora in young cattle and sheep fed concentrate rations which results in the development of ruminal acidosis. These rations may also allow for the development and growth of thiaminase-producing bacteria which, combined with a smaller net synthesis of thiamin in the rumens of concentrate-fed ruminants, could explain the higher incidence in feedlot animals. Experimentally PEM has been produced in lambs by continuous intraruminal infusion of a highly fermentable diet. Animals changed very rapidly to high concentrate rations develop increased ruminal thiaminase levels.

The possibility that intraruminal thiaminases may also create thiamin analogs capable of acting as thiamin antimetabolites and accentuating the disease has been studied but the results are inconclusive. The presence of naturally occurring second substrates (cosubstrates) in the rumen could produce, by the thiaminase type I reaction, a potent thiamin antimetabolite capable of accentuating the condition. In vitro studies have shown that thiaminase only caused rapid destruction of thiamin when a second substrate was added, and a large number of drugs commonly used as anthelmintics or tranquilizers may be active as second substrates. Many compounds found in the rumen of cattle are potential cosubstrates.

Amprolium has been used extensively to produce the lesions in the brains of cattle and sheep that are indistinguishable from the naturally occurring disease.[1] However, since amprolium has been found in the brain tissue, the experimental disease should perhaps be known as 'amprolium poisoning encephalopathy'. The administration of other antagonists such as oxythiamin and pyrithiamin does not produce the disease. This suggests that polioencephalomalacia is a particular form of thiamin deficiency in which the supply of thiamin is reduced by the action of intraruminal thiaminase. Thus, the thiamin status of the animal will be dependent on dietary thiamin intake, thiamin synthesis, the presence of thiaminase in the rumen and the effects of possible antimetabolites. Subclinical states of thiamin deficiency probably exist in apparently normal cattle and sheep being fed diets which are conducive to the disease. This suggests that in outbreaks of the disease the unaffected animals of the group should be considered as potential new cases and perhaps treated prophylactically.

Thiamin is an essential component of several enzymes involved in intermediary metabolism and a state of deficiency results in increased blood concentration of pyruvate, a reduction in the lactate to pyruvate ratio and depression of erythrocyte transketolase. These abnormalities affect carbohydrate metabolism in general, but in view of the specific requirements of the cerebral cortex for oxidative metabolism of glucose, it is possible that a thiamin inadequacy could have a direct metabolic effect on neurons.[1] The brain of the calf has a greater dependence on the pentose pathway for glucose metabolism, in which pathway the transketolase enzyme is a rate-limiting enzyme. Ultrastructural examination of the brain of sheep with the natural disease reveals that the first change which occurs is an edema of the intracellular compartment, principally involving the astrocytes and satellite cells. This is followed by neuronal degeneration which is considered secondary. It has been suggested that the edema may be due to a reduction in ATP production following a defect of carbohydrate metabolism in the astrocyte. There are three basic lesions which are not uniform: compact necrosis, edema necrosis, and edema alone. This may suggest that a uniform etiology such as thiamin deficiency cannot be fully supported.

In the cerebral cortex of affected animals, autofluorescent spots are observed under ultraviolet 365 nm illumination and are a useful diagnostic aid. The distribution of autofluorescence corresponds to that of mitochondria in cerebrocortical neurocytes in affected calves, suggesting that metabolic impairment occurs and the autofluorescent substance is produced in the mitochondria.[24] Mitochondrial swelling and disorganization of cristae are also observable in brain tissue, but are not specific to polioencephalomalacia.

Sulfate-induced polioencephalomalacia

Diets high in sulfur result in hydrogen sulfide production in the rumen and anaerobic bacteria from rumen samples of cattle fed high-carbohydrate, short fiber diets with added sulfate will generate hydrogen sulfide in rumen fluid broth medium.[18,25] Rumen microflora adapt to higher dietary sulfate content over a period of 10–12 days before they are capable of generating potentially toxic concentrations of sulfide.[26] In experimental sulfate diets which induce PEM, the rumen pH decreases during the transition to the experimental diet and acidic conditions in the rumen favor increased rumen gas cap concentrations of hydrogen sulfide. With a change of pH from 6.8 to 5.2, the percent hydrogen sulfide in the rumen gas cap increased from 47 to 97%.[7]

If ruminants inhale 60% of eructated gases, inhalation of hydrogen sulfide could be a route of systemic sulfide absorption,

in addition to gastrointestinal absorption.[21] Sulfide inhibits cellular respiration leading to hypoxia which may be sufficient to create neuronal necrosis in polioencephalomalacia. The nervous system lesions of sulfur toxicosis are indistinguishable from lesions in the naturally occurring disease.

Acute cerebral edema and laminar necrosis

Acute cerebral edema and laminar necrosis occur and the clinical signs are usually referable to increased intracranial pressure from the edema, and the widespread focal necrosis. Recovery can occur with early treatment which suggests that the lesions are reversible up to a certain point. ECGs of buffalo calves with amprolium-induced PEM found decreased frequency patterns, occasional spindles and decreased voltage patterns during the onset of clinical signs. In the comatose stage, there was little evidence of electrical activity. EEGs of animals treated with thiamin hydrochloride found normal awake patterns.[27]

CLINICAL FINDINGS

Cattle

Animals may be found dead without premonitory signs especially in beef cattle on pasture.[2] The clinical findings are variable but characteristically, there is a sudden onset of **blindness, walking aimlessly, ataxia, muscle tremors**, particularly of the head with ear twitching, **champing of the jaws** and frothy salivation, **head-pressing**, and the animal is difficult to handle or move. Dysphagia may be present when one attempts to force feed hay by hand. Grinding of the teeth is common. Initially, the involuntary movements may occur in episodes, and convulsions may occur, but within several hours they become continuous. The animal usually then becomes recumbent, and there is marked opisthotonos, nystagmus, clonic-tonic convulsions, particularly when the animal is handled or moved, and tetany of the forelimbs is common. The temperature is usually normal but elevated if there has been excessive muscular activity. The heart rate may be normal, subnormal, or increased and is probably not a reliable diagnostic aid.

Rumen movements remain normal for a few days, which is an important distinguishing feature from lead poisoning in which the rumen is static.

The **menace reflex is always absent** in the acute stage and its slow return to normal following treatment is a good prognostic sign. The **palpebral eye-preservation reflex is usually normal**. The pupils are usually of normal size and responsive to light. In severe cases the pupils may be constricted. Dorsal strabismus due to stretching of the trochlear nerve is common. Nystagmus is common and may be vertical or horizontal. Optic disc edema is present in some cases but is not a constant finding.

Calves 6–9 months of age may die in 24–48 hours, while older cattle up to 18 months of age may survive for several days. Recovery is more common in the older age group.

In less severe cases, affected animals are blind, head-press into walls and fences, and remain standing for several hours or a few days. In outbreaks, some cattle will be sternally recumbent; others remain standing with obvious blindness, while others are anorexic, mildly depressed, and have only partial impairment of eyesight. Those with some eyesight will commonly return to almost normal. Some survivors are permanently blind to varying degrees but may begin to eat and drink if provided with assistance. Some cases will recover following treatment and may grow and develop normally.[3]

Evidence of recovery within a few hours following treatment with thamin indicates that the disease is associated with thiamin inadequacy. A failure of response indicates the possibility of sulfur toxicity polioencephalomalacia.

Sheep

Sheep usually begin to wander aimlessly, sometimes in circles, or stand motionless and are blind, but within a few hours they become recumbent with opisthotonos, extension of the limbs, hyperesthesia, nystagmus, and periodic tonic-clonic convulsions. Hoggets affected at shearing time may show blindness and head-pressing but, if fed and watered, usually recover within a few days. Occasional animals show unilateral localizing signs, including circling and spasmodic deviation of the head. In goats, early signs may include excitability and elevation of the head. Blindness, extreme opisthotonos, and severe extensor rigidity and nystagmus are common.

In sulfur-induced PEM in sheep introduced to a diet containing 0.43% sulfur, clinical signs occurred 15–32 days later and consisted of depression, central blindness, and head-pressing, but no hyperesthesis, nystagmus, or opisthotonos were observed.[11] In sulfur toxicity in lambs with PEM, the rumen contents may have a strong odor of hydrogen sulfide (rotten egg smell).[17]

There are some reports from Australia of unthriftiness in unweaned and weaned lambs being associated with thiamin deficiency due to the presence of thiaminases in the alimentary tract.[5] In affected flocks the incidence of illthrift in lambs is much higher than the usual incidence and other causes of unthriftiness were ruled out. Affected lambs lose weight, may have chronic diarrhea, and become emaciated and die from starvation. In some flocks, clinical signs of PEM may occur in a small percentage of animals. The disease occurs most commonly in early July which is the coldest part of the year in Australia for lambs which are born in May and June. In affected lambs the fecal thiaminase levels are high and the blood transketolase level activity is increased above normal. Treatment of affected lambs with thiamin resulted in an increase in growth rate.[5]

CLINICAL PATHOLOGY

Thiamin status and metabolism

The biochemical changes occurring in cattle and sheep with the thiamin-deficiency PEM have not been well-defined diagnostically based on thoroughly investigated naturally occurring clinical cases. However, some estimates are available including the changes which occur in the experimental disease. Interpretation of the values may also be unreliable if the animals have been treated prior to death.

The **erythrocyte transketolase activity** is decreased and the thiamin pyrophosphate (TPP) effect is increased. The erythrocyte transketolase activities in normal sheep will range from 40 to 60 iμ/mL red blood cells. A TPP effect of 30–50% is commonly found in normal healthy cattle and sheep and an increase to above 70–80% occurs in animals with polioencephalomalacia.

The **thiamin concentrations** of blood of animals with polioencephalomalacia have varied widely and may be difficult to interpret because of the possibility of thiamin analogs inducing deficiency even when blood thiamin levels are normal. However, this would not apply when blood thiamin levels are below normal. A normal reference range of 75–185 nmol/L is suggested for both cattle and sheep, and levels below 50 nmol/L are considered indicative of deficiency.[28] In normal goats, the mean thiamin content of blood was 108 nmol/L, with a range of 72–178 nmol/L.[12] In goats with polioencephalomalacia, blood thiamin levels were less than 66 nmol/L with a mean of 29 nmol/L. Levels as low as 1.8–3.6 μg/dL (6–12 nmol/L) have been found in suspected cases of polioencephalomalacia. The thiamin concentrations of liver, heart, and brain of cattle and sheep with polioencephalomalacia are decreased. The levels of blood pyruvate and lactate are also increased and thiamin pyrophosphate-dependent enzymes such as pyruvate kinase are decreased.[3] The thiaminase activity of the feces is increased.[5]

The hemogram is usually normal; the total and differential leukocyte counts may indicate a mild stress reaction, a finding which may be useful in differentiation

from encephalopathies due to bacterial infections.

Cerebrospinal fluid pressure taken at the cysterna magna is increased from a normal range of 120–160 mm saline to levels of 200–350 mm. The level of protein in the CSF may be normal to slightly or extremely elevated. A range from 15 to 540 mg/dL with a mean value of 90 mg/dL in affected cattle is recorded. There may also be a slight to severe pleocytosis in the CSF in which monocytes or phagocytes predominate.

Ruminal sulfide measurement. Changes in rumen gas cap H_2S concentrations are larger than changes in rumen fluid H_2S concentrations and estimation of rumen gas H_2S concentration may be a practical method of detecting pathological increases in ruminal hydrogen sulfide gas.[29,30] A simple, rapid, minimally invasive method may be useful for estimating the H_2S concentration of ruminal gas under field conditions. A sterile 8.9 cm 18 g needle with stillete is introduced into the gas cap of the rumen by way of the left paralumbar fossa. The needle is then connected to calibrated H_2S detector tube. In cattle, with sulfate-induced polioencephalomalacia, increases in ruminal gas H_2S may be as high as 100 times more than control animals.[29]

Brain function. The effects of high dietary sulfur on brain function have been examined using evoked potentials techniques.[31] Altered nerve conduction pathways occur in sheep fed high sulfur diets without supplemental thiamin compared to animals which have received thiamin.[31] The visual evoked potentials are abnormal in ruminants with thiamin-responsive polioencephalomalacia.[32]

NECROPSY FINDINGS

Diffuse cerebral edema with compression and yellow discoloration of the dorsal cortical gyri is evident and the cerebellum is pushed back into the foramen magnum with distortion of its posterior aspect.

In recovered animals, there is macroscopic decortication about the motor area and over the occipital lobes. The lesion can be identified grossly using ultraviolet illumination which results in a fluorescence that indicates necrosis of brain and engulfment of necrotic tissue by lipophages. In general, there is a good correlation between the presence of characteristic fluorescence and the biochemical changes in cases of polioencephalomalacia. A small percentage of false negatives may occur.

Histologically the lesions are widespread but most common in the cerebral cortex. There is bilateral laminar necrosis and necrosis of deeper cerebral areas. The necrosis is most prominent in the dorsal occipital and parietal cortex, but bilateral areas of necrosis are also seen less frequently in the thalamus, lateral geniculate bodies, basal ganglia, and mesencephalic nuclei. Lesions of the cerebellum are also present. The severity and distribution of the lesions probably depend on the interrelationships between clinical severity, age of affected animal, and length of illness before death.

Subnormal levels of thiamin are detectable in the liver and brain of calves with the natural disease and low levels are also found in the experimental disease.[21] In the molasses-induced disease in Cuba, the tissue thiamin levels were within the normal range.

In some cases of sulfur-associated polioencephalomalacia, the rumen contents have a strong odor of hydrogen sulfide – the rotten egg smell.

DIFFERENTIAL DIAGNOSIS

None of the biochemical tests described under clinical pathology is practical. The diagnosis must be made on the basis of clinical findings and the readily available simple tests which rule out other diseases that resemble polioencephalomalacia. A careful consideration of the epidemiological history often assists in the diagnosis.

Cattle

The differential clinical diagnosis for cattle is summarized in Table 32.3.

Polioencephalomalacia in cattle occurs primarily in young growing animals 6–9 months of age on concentrate rations and is characterized clinically by a sudden onset of blindness, muscular tremors of the head and neck, head-pressing, nystagmus, and opisthotonos. The disease also occurs in mature beef cattle on pasture containing a high level of sulfate in their water and feed.

In cattle the disease must be differentiated from:

- **Acute lead poisoning** which is most common in calves after spring turnout but occurs in adult cattle too and is characterized by central blindness, tremors, convulsions, uncontrollable activity with bellowing, champing fits, hyperexcitability, rumen stasis, and death in several hours. Early treatment may be successful
- **Subacute lead poisoning** characterized by blindness, stupor, head pressing, rumen stasis, weak palpebral reflexes, and no response to therapy
- **Hypovitaminosis-A** characterized by a history of a vitamin A deficient diet and nyctalopia, peripheral blindness, dilated and fixed pupils, optic disk edema, and transient convulsions followed by recovery
- **Histophilus meningoencephalitis** characterized by sudden onset of ataxia, recumbency, fever, depression with eyes closed, lesions of the fundus, marked changes in hemogram, enlarged joints, and death in several hours if not treated eary.

Sheep

In sheep polioencephalomalacia must be differentiated from:

- **Enterotoxemia (pulpy kidney disease) due to *Cl. perfringens* type D** in unvaccinated sheep, especially feedlot lambs, in which the clinical findings are almost identical; it occurs under the same management conditions as polioencephalomalacia. Enterotoxemia in lambs usually develops within several days after being placed on a grain ration, whereas polioencephalomalacia occurs after several weeks of grain feeding. Glycosuria in pulpy kidney disease may assist the diagnosis but a necropsy is usually more informative
- **Focal symmetrical encephalomalacia** also resembles polioencephalomalacia but is sporadic, usually involves only a few animals and will not respond to treatment.

Goats

In goats the disease must be differentiated from caprine leukoencephalomyelitis, listeriosis, enterotoxemia, pregnancy toxemia, lead poisoning, and meningoencephalitis.

TREATMENT

Thiamin hydrochloride

The treatment of choice for thiamin deficiency PEM is thiamin hydrochloride at 10 mg/kg BW IV initially and followed by similar doses every 3 hours for a total of 5 treatments. When treatment is given within a few hours of the onset of signs, a beneficial response within 1–6 hours is common and complete clinical recovery can occur in 24 hours. Goats and sheep will commonly respond within 1–2 hours. For those which take longer to recover, the eyesight and mental awareness will gradually improve in a few days and the animal will usually begin to eat and drink by the third day after treatment. Rumen transplants of rumen juice from roughage-fed cattle may improve appetite and rumen function in those responding slowly. In sheep, following treatment with thiamin the blood transketolase activity begins to return to normal in 2–4 hours and is considered normal 24 hours after treatment.

Some cattle improve to a subnormal level within a few days and fail to continue to improve. These are usually affected with diffuse cortical and subcortical necrosis and will usually not improve further in spite of continued treatment. Those which return to a clinically normal state will usually do so by 48 hours or sooner after initial treatment. Those which are still clinically subnormal and anorexic by the end of the third day will usually remain at that level and should be slaughtered for salvage.

Treatment is ineffective in advanced cases, but unless an accurate history is

available on the length of the illness, it is usually difficult to predict the outcome until 6–12 hours following treatment. Thus, it is usual practice to treat most cases with thiamin at least twice and monitor the response. If there is no beneficial response in 6–8 hours, emergency slaughter for salvage should be considered.

The oral administration of thiamin or thiamin derivatives is indicated when thiaminases are thought to be in the alimentary tract. Thiamin hydrochloride at a rate of 1 g for goats and lambs and 5 g for calves, in a drench, is recommended. However, because the action of thiaminase type I on thiamin may result in the production of thiamin analogs which may act as inhibitors of thiamin metabolism, the use of thiamin derivatives which are resistant to thiaminases, lipid soluble and absorbed from the intestine are being explored as therapeutic and prophylactic agents. Thiamin propyldisulfide can depress the thiaminase activities in the ruminal fluid of sheep with polioencephalomalacia within 2 hours after oral administration. The blood pyruvate levels and transketolase activities are also restored to normal and treated animals recovered clinically.

Outbreak management

In outbreaks, the in-contact unaffected animals on the same diet as the affected animals may be on the brink of clinical disease. The diet should be changed to one containing at least 50% roughage or 1.5 kg of roughage per 100 kg BW. Thiamin may be added to the ration at the rate of 50 mg/kg of feed for 2–3 weeks as a preventive against clinical disease, followed by a level of 20–30 mg/kg of feed (cattle and sheep) if the animals remain on a diet that may predispose them to the disease.

Sulfur toxicity polioencephalomalacia

There is no specific treatment for PEM caused by sulfate toxicity. The use of thiamin hydrochloride in doses given above is recommended.[7]

CONTROL

Thiamin supplementation

A rational approach to the control of PEM associated with thiamin inadequacy is to supplement the rations of concentrate-fed cattle and sheep with thiamin on a continuous basis. The daily requirements for protection have not been determined using controlled feeding trials but a rate of 3 mg/kg DM of feed for cattle and sheep has been recommended. This level may not be protective in all situations and response trials may be necessary to determine protective levels for different situations. Levels up to 20–30 mg/kg of feed may be necessary for protection. Most natural feedstuffs for ruminants contain thiamin at about 2 mg/kg DM which when combined with the thiamin synthesized in the rumen will meet the requirements. However, the presence of thiaminases in the rumen will necessitate dietary supplementation with thiamin, but the optimal amount that will provide protection under practical conditions is uncertain.

The IM injection of 500 mg thiamin 3 times weekly into 6-month-old calves raised under practical farm conditions will steadily reduce the percentage thiamin pyrophosphate effect to zero in about 6 weeks. The daily oral administration of 100 mg thiamin to young calves fed initially on milk substitutes and then on concentrates and hay results in a decrease in percentage pyrophosphate effect.

For animals which are fed diets associated with thiamin inadequacy, it is recommended that thiamin be added to the diet at the rate of 5–10 mg/kg DM.[12] Cattle and sheep on concentrate-fed rations must also receive supplements containing all necessary vitamins and minerals, especially cobalt, a deficiency of which may be associated with some outbreaks of the disease.

Feeding roughage

The minimum amount of roughage which should be fed to feedlot cattle and sheep in order to prevent the disease and still maintain them on high levels of concentrates is unknown. A level of 1.5 kg of roughage per 100 kg BW has been recommended but this may not be economical for the feedlot whose profits are dependent on rapid growth in grain-fed cattle. Supplementation of the diet with thiamin appears to be the only alternative.

The prevention of the disease in sheep which are being moved long distances or gathered together for shearing and other management practices will depend on insuring an ample supply of roughage and water and avoiding drastic changes in management.

Sulfate toxicity PEM

The prevention of the disease associated with a high sulfur intake in the feed and water supplies will depend on analysis of the feed and water for sulfate and making appropriate adjustments in the sources of feed and water in order to decrease the intake of sulfur to safe levels.

EQUINE NEONATAL ENCEPHALOPATHY (NEONATAL MALADJUSTMENT SYNDROME OF FOALS, DUMMY FOAL, BARKERS, AND WANDERERS)

This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure to suckle, abnormal behavior, seizures, through coma in otherwise apparently healthy foals.

ETIOLOGY

A number of diseases cause the clinical signs consistent with this syndrome. These include antenatal, natal or postnatal hypoxia, congential and metabolic anomalies, placental abnormalities, intracranial hemorrhage, prematurity, and thoracic trauma.[1] Of these causes, hypoxia before, during or soon after birth is considered the most common cause of neonatal encephalopathy, although hypoxia is rarely documented. It is important to realize the neonatal encecphalopathy is one of many manifestations of hypoxia of the fetus or neonate, the other manifestations including gastrointestinal and renal damage.[2,3]

EPIDEMIOLOGY

The disease is sporadic and occurs worldwide with an annual **incidence** in foals of approximately 1%.[4] Foals of either sex and of any breed born to mares of any age

Table 36.2 Differential diagnosis of comatose ('sleeper') neonatal foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Lesions	Treatment and prognosis
Actinobacillus equuli septicemia	Foals to 3 months but usually <2 weeks. Enzootic to some farms.	Sudden onset recumbency, fever, abdominal pain, diarrhea, joint distension. Death.	*A. equuli* in blood or joint fluid	Septicemia, septic synovitis/arthritis, nephritis with abscesses in renal cortex.	Penicillin and gentamicin or other broad spectrum antibiotic, supportive care. Fair prognosis if treated early.
Septicemia	*E. coli, Klebsiella* sp., *Streptococcus* sp., *Salmonella* sp., *Actinobacillus suis*, Equine herpesvirus-1. Failure of transfer of passive immunity.	Abrupt onset of depression, fever, failure to nurse and recumbency. Later diarrhea, pneumonia and joint distension.	Culture of organism from blood or lesions (joints, lungs, feces).	Consistent with septicemia. Pneumonia. Septic synovitis, arthritis, osteomyelitis.	Broad spectrum antibiotics, supportive care (see 'Principles of providing care to the critically ill neonate'). Guarded to poor prognosis.
Isoimmune hemolytic anemia	Incompatible mating of Aa+ or Qa+ stallion with negative mare.	Normal at birth. Subsequent depression, cessation of nursing, exercise intolerance, icterus, anemia. Hemoglobinuria in severe cases.	Positive Coomb's test to demonstrate immunoglobulin on foal's red cells. Dam's colostrum agglutinates or lyses foal red cells.	Anemia, icterus. Death due to anemic hypoxia.	Transfusion of washed dam's red blood cells or of compatible donor (check dam's plasma with donor's red cells). Fair prognosis.
Uroperitoneum	Ruptured bladder, urachus or ureteral defect. Colts 1 to 3 days of age. Foals of either sex with other systemic diseases.	Normal at birth. Onset of abdominal distension, mild colic, depression and recumbency. May urinate small volumes.	Peritoneal fluid has high creatinine concentration. Hyperkalemia, hyponatremia, hypochloremia.	Uroperitoneum. Rupture bladder, urachus or ureter.	Surgical correction AFTER drainage of abdomen and resolution of hyperkalemia with intravenous dextrose or 0.9% NaCl. Good prognosis with appropriate care.
Hypogylcemia	Failure to nurse. Rejection by mare. Mare has no milk (agalactia)	Normal at birth, repeated attempts to nurse. Gradual onset (hours) of weakness and depression.	Low blood glucose concentration (<60 mg/dL, 3 mmol/L).	None. No food in stomach.	Excellent response to feeding or intravenous glucose.
Neonatal maladjustment syndrome	Sporadic	Onset of abnormal behavior, recumbency, failure to nurse or orient to mare. Aimless wandering and vocalization.	None characteristic. Frequently failure of transfer of passive immunity.	Usually none apparent. Occasional intracranial vascular accidents.	Supportive care (see 'Principles of providing care to critically ill neonates'. Good prognosis.
Congenital defects	Sporadic	Depends on nature of cardiac, gastrointestinal or central nervous system defect.	None	Consistent with defect.	Usually no treatment. Poor prognosis depending on defect.

or reproductive history can be affected. The **case fatality rate** is very low for appropriately treated foals without other systemic illness.

PATHOGENESIS

It is speculated that hypoxia resulting from intracranial vascular accidents,[5] asphyxia at birth or placental insufficiency before birth damages the central nervous system. Neurological abnormalities and a failure to nurse, result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia.

CLINICAL SIGNS

Foals that are abnormal at birth can display a range of behavioral abnormalities, from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, and have no affinity for the mare and are unable to locate the udder or teat. Aimless wandering and a characteristic 'barking' vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonos with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling.[1] Between episodes foals are usually depressed or somnolent. Affected foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39°C, 102°F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) through to grand mal seizures.

Foals that are normal at birth may develop signs by 24 hours of age. The signs are similar to those described above, with the exception that the foals are initially able to ambulate. It is important to realize that healthy newborn foals lack a mence reflex, have a hypermetric gait and intention tremor, and become flaccid when restrained.

Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4–6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of cerebrospinal fluid should be performed in any foal with signs of CNS dysfunction in the presence of fever or other signs of sepsis.

CLINICAL PATHOLOGY

There are no hematological or serum biochemical abnormalities characteristic of the disease:

- Affected foals usually have **failure of transfer** of maternal immunoglobulins (serum IgG <400 mg/dL)
- They may be **hypoglycemic** (<80 mg/dL, 4 mmol/L)
- **Cerebrospinal** fluid is often normal, although it may contain red blood cells or apper xanthochromic as a result of bleeding.

DIAGNOSTIC CONFIRMATION

Definitive diagnosis of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs, and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologicially, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex.[6] Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Many affected foals have evidence of intracranial vascular accidents.[7] Affected foals that are euthanased often have no detectable lesions in the brain.

Samples for post-mortem diagnostic confirmation

Formalin-fixed brain, including cerebral cortex, cerebellum and brain stem, and lung for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurological or behavioral abnormalities in foals including: sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturity, or immaturity.

TREATMENT

The principles of treatment are:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage
- Correction of failure of transfer of passive immunity
- Nutritional support and general nursing care. The management of affected foals is mainly supportive and is time consuming and labor intensive.

Provision of nutritional support, treatment of failure of passive transfer of maternal immunoglobulins, and nursing care is dealt with in detail in the section 'Principles of care of the critically ill neonate'.

For other than emergency treatment of seizures, in which **diazepam** (0.1–0.4 mg/kg, intravenously, as required) or **midazolam** (0.05–0.1 mg/kg IV, as required) are useful, **phenobarbital** (phenobarbitone), **phenytoin** and **primidone** are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 1–3 mg/kg intravenously in 30 mL of isotonic saline infused over 15–30 minutes. Maintenance therapy is a similar dose intravenously or orally, every 8 hours, and the dose adjusted to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half life of phenobarbitol in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved administration of phenobarbitol can be discontinued. Drug concentrations will be at or above the target concentration (5–30 μg/mL) for several days after the final dose. **Phenytoin** (5–10 mg/kg intravenously or orally initially, then 1–5 mg/kg every 4 hours) or **primidone** (20–40 mg/kg orally every 12–24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as magnetic resonance imaging or computed tomography (CT).[8] However, treatment is often initiated on the basis of clinical signs. None of the treatments have demonstrated efficacy, and some are controversial. **Dimethyl sulfoxide** (DMSO) is given intravenously at 0.5–1 mg/kg once or twice daily for 3 days as a 10% solution. **Mannitol** (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema but is contraindicated if intracranial hemorrhage is present. **Glucocorticoids** (dexamethasone, 0.2–1 mg/kg or prednisone, 1–2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

Magnesium sulfate (0.05 mg/kg per hour for one hour, then 0.025 mg/kg/h IV for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered caffeine (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours).[3] Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

Good nursing care is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly.

Affected foals can require up to 4–6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

CONGENITAL TREMOR SYNDROMES OF PIGLETS

Tremors in pigs are not a common clinical sign. Recently, generalised tremors have been described in grower pigs[1] but until this report the condition has only been described as a neonatal condition. The condition has been known for a long time in Britain.

This group of at least four etiologically distinct congenital diseases of the nervous system has a similar clinical and pathological identity. In particular they all have congenital tremor (myoclonia congenita) and these rhythmic tremors are most evident while the piglet is standing, are reduced when it lies down, and disappear when it is asleep. It is therefore not encephalitis but an increased sensitivity of the spinal cord reflexes.

Although the tremor is present at birth it may not be observed until the piglets are 2 or 3 days old and beginning to move about actively. The tremor varies from a very rapid twitch affecting only the head to a slow tremor causing the pig to 'dance'; there may be such a severe tremor that the body and head tremble violently and rock from side to side. There is no muscular weakness and the piglets get up and scamper about, but there may be ataxia and dysmetria so that the gait may be badly affected. Mildly affected piglets are not greatly incapacitated and can survive and eventually recover in 2–8 weeks; the tremor fades gradually, and near the end of the course it may be evident only during exercise. Badly affected piglets may be unable to get to the teat to suck and may die of starvation. Many are fatally crushed or trampled by the sow.

For convenience, entities within the syndrome have been classified into two types.

Type A has morphological lesions and there are 5 types AI, AII, AIII, and AIV for which the causes are known.

Type AI (*myoclonia congenita*) results from transplacental infection of the fetus by particular strains of swine fever virus.[2–4] In litters affected by swine fever virus usually about 40% of the litter is affected. The characteristic lesions are cerebellar hypoplasia and cerebrospinal dysmyelinogenesis. When the disease caused by the unidentified viral infection of the fetus first appears in a piggery all litters are affected. Most pigs in each litter have the disease, but after a period of several months the disease disappears, apparently because of herd immunity. The principal sign as in the swine fever induced disease is myoclonia, and most piglets recover. Spinal dysmyelinogenesis is the characteristic lesion.

Type AII (*myoclonia congenital*) is caused by transplacental infection with an agent presumed to be a virus and it is believed to be the most common type of congenital tremor.

Type AIII (congenital cerebrospinal hypomyelinogenesis) is a hereditary form so far found only in Landrace and known as Landrace trembles.[5] The inherited sex-linked disease occurs in the progeny of Landrace or Landrace-cross sows. Up to 11% of Landrace piglets may be affected compared to only 0.3–0.8% in the Yorkshire, Hampshire, and Duroc breeds. The mode of transmission is via a monogenic sex-linked recessive character, and half of all male pigs born are affected. Histologically, there is cerebrospinal myelinogenesis. Most affected pigs die. It is essentially a deficiency of oligodendrocytes.

Type AIV is also a genetically determined condition due to an autosomal recessive condition found in Saddlebacks. It is seen in about 25% of the progeny, and is fatal in most of them. Cerebrospinal dysmyelinogenesis is the characteristic lesion. It is characterised by a deficiency of myelin throughout the CNS.[6] A type distinct from this has also been reported in Saddleback x Large White sows.[7]

Type AV occurs naturally in Scandinavia[8] and is characterized by cerebellar hypoplasia and has been experimentally produced following dosing of pregnant sows between 45 and 75 days of gestation with trichlorfon.[9]

Type B is a form of congenital tremor not yet adequately characterized and without morphological lesions and is of unknown etiology. The differentiation of these diseases is now possible on the basis of histopathological and neurochemical findings and relating these to the epidemiological data. In piglets born from sows inoculated with the Weybridge congenital tremor strain of the swine fever virus in early pregnancy, the severity of the clinical signs was related to the degree of spinal myelin deficiency. Semiautomated planimetry can be used to determine the cross-sectional areas of spinal gray and white matter of affected piglets. The spinal cord cross-sectional area is significantly reduced in piglets affected with Type AI congenital tremor. The reduction is similar to Type AII. The neurochemical findings relate to the presence of particular fatty acid profiles in the cholesterol esters in the lipids of the spinal cord.

Control of the disease depends on its cause. If it is inherited the recommended procedure is to keep none of the affected recovered pigs for breeding. If the cause is one of the maternal infections of early pregnancy it is recommended practice to deliberately expose empty females to affected piglets so that they become immunized before pregnancy. Failure to identify the cause may necessitate adopting both procedures.

The disease appears to occur sporadically but when it does occur it may assume great importance. As many as 15% of litters born in a piggery may be affected, and of these 72% of the piglets may be affected and the case fatality rate amongst these may be as high as 50%. There is a feeling amongst veterinarians that the condition has increased recently but this may just be an increased awareness. If there is an increase, the specific cause of the increased prevalence has not been identified but it is possibly the unidentified virus referred to above: the virus of congenital tremor Type AII. There is also the possibility that the observed concurrent increase in prevalence of both splayleg and congenital tremor may indicate that they are possibly caused by the same virus. In this context, there is conjecture, that the PCV2 virus which is extremely small and similar in size to the particles that were described in the early electron micrographs of the spinal cord of affected piglets may be responsible. As yet there is no confirmation that splayleg and congenital tremor are PCV2 associated disorders.[10]

OVINE HUMPYBACK

This is a disease of sheep, mainly Merino wethers, in western Queensland, characterized by stiffness and shortness of steps when forced to walk for about a kilometer. The sheep stops walking and adopts an arched back posture. At this time the body temperature is significantly elevated and the level of lymphocytes in the blood is lowered. The greatest incidence is in summer after rain and when the sheep are in full wool, and the hyperthermia and ataxia disappear when the sheep are shorn. Environmental temperatures at the time of the greatest prevalence of the disease are high,

commonly 40°C. This occurs in spite of the presence of a characteristic degeneration of spinal cord tracts.[1] The obvious explanation of the phenomenon is that it is a form of heat stroke and that the nervous system lesions are incidental.

EQUINE CERVICAL VERTEBRAL STENOTIC MYELOPATHY, (WOBBLER, 'WOBBLES', EQUINE SENSORY ATAXIA, CERVICAL VERTEBRAL INSTABILITY)

Synopsis

Etiology Unknown.
Epidemiology Sporadic or endemic disease of young horses. Young, rapidly growing male horses are most commonly affected. Separate presentation in middle-aged horses in which it is sporadic.
Clinical signs Spinal ataxia evident as truncal sway, ataxia and paresis usually more severe in the hind limbs. Radiographic evidence of narrow spinal canal.
Clinical pathology None.
Lesions Malacia and Wallerian degeneration in the cervical spinal cord.
Differential diagnosis Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis, West Nile encephalomyelitis, equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, congenital vertebral malformation, diskospondylitis, and rye-grass staggers.
Diagnostic confirmation Radiography. Positive contrast myelography. Necropsy.
Treatment Anti-inflammatory drugs. Surgical fusion of vertebrae.
Control None.

ETIOLOGY

The cause of neurologic disease is compression of the cervical spinal cord, hence the term compressive myelopathy. The compression may be **static**, that is the compression is present constantly with the neck in a neutral position, or **dynamic** and only present intermittently when the neck is either flexed or extended. The second situation is often referred to as cervical vertebral instability. The etiology of equine cervical stenotic myelopathy (CSM) in most cases is not known. Several basic syndromes of compressive myelopathy, based on age of occurrence, are recognized:

- Equine stenotic myelopathy (ESM) in immature horses (<3 years of age, depending on breed) that is often associated with developmental joint disease in the axial and appendicular skeleton. The fundamental underlying defect appears to be a narrow diameter of the cervical vertebral canal.
- Cervical vertebral instability (CVI), a disease of horses less than 1 year of age, is often associated with malformations of one or more of the cervical vertebrae.[1]
- Compressive myelopathy in mature horses, >4 years (usually >7 years) of age, associated with osteoarthritis of the articular facets of the caudal cervical vertebrae, with subsequent impingement of the vertebral canal by bony and soft tissue proliferative lesions.
- Miscellaneous causes of cervical cord compression by neoplasia (melanoma, sarcoma, lymphoma),[2–4] trauma (cervical vertebral fractures), arachnoid or synovial cysts[1] or, rarely, discospondylitis.[5]

An alternative categorization is based on the nature of the bony lesion and not on the cause of compression of the spinal cord. **Type 1 cervical vertebral malformation** occur in horses <2 years of age that have vertebral changes that likely began in the first few months of life, and include malformations causing stenosis of the vertebral canal, malformations at the articulations of the vertebrae including osteochondrosis, and enlarged physeal growth regions.[6] **Type II cervical vertebral malformations** tend to occur in older horses with severe osteoarthritic lesions of the vertebral articulations.[6]

EPIDEMIOLOGY

Occurrence

The disease in mature horses occurs sporadically throughout the world.

The disease in young horses is sometimes endemic on farms or studs, and in particular lines of horses. There is a suggestion of a familial tendency for the disease, although this has not been well documented.

The **morbidity rate** may be as high as 25% of each foal crop on individual Thoroughbred farms, although the overall frequency of the disease in the general horse population is much lower.[7]

Risk factors

Animal risk factors

The disease in young horses is commonly recognized in Thoroughbred, Standardbred, Warmblood, and Quarter horses, but other breeds can be affected. Ponies are rarely, if ever, affected. The disease occurs in horses less than 4 years of age, with most cases occurring in 1–3-year-old horses. Males are more commonly affected than are females. Horses with cervical stenotic myelopathy have a narrower spinal canal than do unaffected animals and this condition, with degenerative joint disease of the articular facets and thickening of the ligamentum flavum, contributes to the greater likelihood that the horse will have spinal cord compression.[7–9]

It is suspected that predisposition to the disease is heritable, but this has not been demonstrated by appropriate studies. The stenotic myelopathy is believed to be the result of a combination of fast growth rate and over nutrition, and dietary restriction may reduce the incidence of the disease.[7] A relationship of ESM to developmental bone disease (osteochondrosis) and dietary copper has been suggested, but is unproven.

The disease in mature horses tends to be in horses used for athletic endeavours, and is uncommon in brood mares or retired animals.

PATHOGENESIS

The disease is attributable to injury to the spinal cord as a result of compression by either soft tissue (joint capsule, intervertebral ligaments, or, rarely, intervertebral disk material) or cartilage and bone.

Constant or intermittent pressure on the spinal cord causes necrosis of white matter and neurons at the site of compression, and degeneration of fibers of ascending tracts cranial to the site of compression, and of descending tracts caudal to the compression.[10] The ascending tracts are those associated with general proprioception whereas the descending tracts are upper motor neurons. These tracts are located superficially in the dorsolateral aspect of the cervical spinal cord and damage to them results in signs of ataxia and weakness. Tracts from the caudal limbs are more superficial, and therefore more easily injured, than ar tracts associated with the cranial limbs. Consequently, clinical signs are usually more severe in the hind limbs. The spinal cord lesions are usually, but not always, bilaterally symmetrical, as are the clinical signs.[10] Proprioceptive pathways are disrupted, causing the signs of ataxia (incoordination) typical of the disease. Clinical signs vary depending on the site of the lesion (see below).

CLINICAL FINDINGS

The onset of clinical signs is sometimes acute in both ESM and CVI in young horses and there may be a history of trauma, such as falling. However, the onset of clinical signs in ESM in both young and mature horses is usually gradual and insidious and in mildly affected horses the nervous disease may be mistaken for lameness of musculoskeletal origin. Affected horses are bright and alert and have a normal appetite. There may be evidence of pain on manipulation of the neck, especially in mature horses, or on firm pressure over the lateral facets.

The severity of clinical signs varies from barely detectable to recumbency. There are no defects of cranial nerves, with the exception of the cervicofacial reflex.

Mildly affected horses may have deficits that are difficult to detect and only apparent under saddle or at high speed. The owner may complain of poor performance of a race horse or dressage animal, of an animal that frequently changes leads or that is poorly gaited. Careful examination may reveal excessive circumduction of the hind feet, stumbling, and pacing when the head is elevated.

Moderately affected animals have truncal sway, the body of the horse and hind quarters swaying laterally when the horse is walked in a straight line, and excessive circumduction of the hind feet. Having the horse move in a very tight circle about the examiner often causes the circumduction to become worse in the outside hind leg and the horse to place one foot on top of the other. Affected horses will sometimes pace when walked in a straight line with the head elevated. Blindfolding the horse does not exacerbate the signs. Affected horses will stumble when walked over low objects, such as a curb, and will **knuckle** at the fetlocks and stumble when walked down a steep hill.

Severely affected horses often fall easily when moved or are unable to stand. The horses are bright and alert, but anxious, and display marked truncal sway and ataxia. When standing they will often have their legs in markedly abnormal positions.

Mature horses with disease secondary to arthritis of the articular facets can have hypalgesia of the skin overlying those regions and atrophy of the cervical musculature.

Horses with lesions in the cervical spinal cord cranial to C6–C7 have signs in both fore and hind limbs. The hindlimbs are more severely affected and the signs are usually, but not always,[10] bilaterally symmetrical. Lesions of the cervical intumescence (C6 to T2) may cause signs that are more severe in the forelimbs than in the hindlimbs. Lesions at this site may also cause signs typical of brachial plexus injury. Focal muscle atrophy is not characteristic of ESM or CVI and there are never signs of cranial nerve, cerebral, or cerebellar disease.

After initial progression the clinical signs usually stabilize or partially resolve. However, complete spontaneous recovery is very unusual. Death is unusual unless it is by misadventure, although many affected animals are killed for humane reasons.

Ancillary diagnostic tests

The 'slap test', in which the response of the arytenoid cartilages to a slap on the thorax is examined through an endoscope, has poorer sensitivity and specificity for detecting spinal cord disease than does a routine neurological examination.[11]

Acupuncture has no proven value in the diagnosis of ESM or CVI and should not be used for this purpose.

Radiographic examination

Radiographic examination of cervical vertebral column of affected horses reveals narrowing of the spinal canal.[7,8] This has diagnostic utility, e.g. a ratio of spinal canal to vertebral body diameter of less than 50% for C4 is associated with a 28-fold increase in the probability of ESM.[8] Other measures of spinal canal diameter are useful in the detection of stenosis and compressive myelopathy.[12–14] Other radiographic signs consistent with ESM or CVI include:

- Encroachment of the caudal vertebral physis dorsally into the spinal canal ('ski jump lesion')
- Extension of the arch of the vertebra over the cranial physis of the next vertebra
- Sclerosis of the spinal canal
- Kyphosis between adjacent vertebra
- Degenerative joint disease of the articular facets.

However, these signs are also common in normal horses and have poor predictive value.[1,8,12,13]

Myelography has been considered to provide the definitive ante mortem confirmation of spinal cord compression.[4] However, the sensitivity of this technique, using a 50% reduction in the width of the dorsal dye column as a cut-off for diagnosis of the disease is 53% (95% confidence interval 34–72%, n = 22) and the specificity is 89% (95% confidence interval of 84–93%, n = 228).[16] Others have found similar values for sensitivity and specificity.[12] These results indicate that a positive finding on myelography is highly suggestive of the disease, but that a negative finding does not eliminate the possibility of the disease. The false-positive rate is increased to 12–27% for compression at mid-cervical sites during neck flexion.[16] Myelography is superior in diagnosing compressive lesions at C6–C7 than at more proximal sites.[16] Occasionally the compression is lateral rather than dorso-ventral and is not readily apparent on routine myelography.

CLINICAL PATHOLOGY

Hematological and serum biochemical values are usually within reference ranges in affected horses. Cerebrospinal fluid from affected horses may have increased protein concentration, but this finding is neither characteristic nor specific for ESM or CVI. However, other causes of spinal ataxia may cause characteristic changes in the cerebrospinal fluid. Measurement of creatine kinase activity in CSF has no diagnostic value in horses.[17]

NECROPSY FINDINGS

Gross examination reveals degeneration of the articular facets in many affected horses.

Impingement of soft tissues, especially the ligamentum flavum and joint structures, or cartilage and osteophytes into the spinal canal may be apparent. The spinal canal may be narrow. The spinal cord may be indented and soft at the site or sites of compression. Histologically, there is nerve fiber swelling, widespread degeneration of myelin, and astrocytic gliosis. Cranial to the compressive lesion, Wallerian degeneration is evident in the dorsal and lateral funiculi, while caudal to the compression these changes are most evident in the ventral and central lateral funiculi.[10] Slight atrophy of cervical muscles is sometimes evident. There is histological evidence of stretching and tearing of the ligamentum flavum and joint capsule at affected joints especially C6 or C7.

DIFFERENTIAL DIAGNOSIS

Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis (*Hypoderma* spp., *Setatia* sp., *Halicephalobus deletrix*), equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, West Nile encephalomyelitis, congenital vertebral malformation (especially in Arabian foals), discospondylitis, tumors involving the spinal canal (melanoma, lymphoreticular neoplasia), and rye-grass staggers. See Table 36.3.

TREATMENT

Medical treatment of the acute disease consists of rest and administration of anti-inflammatory drugs (dexamethasone 0.05–0.25 mg/kg, IV or IM every 24 hours; flunixine meglumine 1 mg/kg, IV every 8–12 hours; phenylbutazone 2.2–4.4 mg/kg, orally every 12–24 hours; and/or dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline, IV every 24 hours for 3 treatments).

Treatment of arthritis of the facets of mature horses can be achieved by injection of the articular facet joints with corticosteroids (40 mg methylprednisolone acetate).[18] Injection of the joint is facilitated by ultrasonographic guidance.[18] Injection of the joints with anti-inflammatory drugs is assumed to result in reduction in inflammation and soft tissue swelling with consequent reduced compression of the cervical spinal cord.

Table 36.3 Differential diagnosis of disease causing spinal ataxia in horses

Disease	Etiology and epidemiology	Clinical signs and lesions	Treatment and prognosis
Cervical compressive myelopathy (cervical stenotic myelopathy, cervical vertebral instability)	Sporadic. Young, rapidly growing males. More common in Thoroughbreds, Standardbreds, and Warmblood horses. Syndrome in mature horses caused by arthritis or articular facets.	Symmetrical ataxia often of sudden onset. May be associated with trauma. Hind limbs most severely affected. Compression of cervical spinal cord demonstrated by myelography. CSF normal.	Medical treatment of rest and antiinflammatory drugs. Poor prognosis. Surgical correction by ventral stabilization. Guarded prognosis.
Equine degenerative myelopathy	Young horses (<3 years). Familial incidence of increased requirement for vitamin E.	Gradual onset symmetric ataxia that stabilizes at about 3 years of age. No radiographic abnormalities in cervical spinal cord. CSF normal.	Vitamin E 5–20 iu/kg per day in feed may prevent progression. No cure. Death uncommon.
Equine protozoal myeloencephalitis	*Sarcocystis neurona* in spinal cord or brain. Americas only. Infectious but not contagious.	Any sign of central nervous system dysfunction. Usually gradual onset of asymmetric spinal ataxia, focal muscle atrophy or weakness. CSF contains antibody to *S. neurona*, but also found in normal horses.	Ponazuril 5–10 mg/kg orally daily for 28 days. Older, but effective, treatment is pyrimethamine, 1 mg/kg orally and sulfadiazine, 20 mg/kg orally every 24 hours for 90–120 days. Nitazoxonide 25 mg/kg orally once daily for 2 days followed by 50 mg/kg orally for 26 days. Vaccination not recommended.
Equine herpesvirus-1 myeloencephalopathy	EHV-1. Infectious and contagious. Sporadic. Outbreaks occur often preceded by fever or upper respiratory tract disease.	Ascending paralysis with fecal and urinary incontinence, recumbency, normal mentation. CSF xanthochromic and increased protein concentration. Lesion is vasculitis and malacia.	Corticosteroids controversial. Nursing care. Poor prognosis. Vaccination minimally effective.
West Nile encephalitis	West Nile virus. Transmitted by bite of infected mosquito. Horse is 'dead end' host and does not develop sustained viremia. Enzootic to Mediterranean littoral and North America. Peak disease risk is late summer.	Weakness, muscle fasciculations, altered mentation. Recumbency.	No specific treatment. Nursing care. Corticosteroids controversial. Hyperimmune serum available in some areas. Interferon has been used but efficacy uncertain.
Trauma	Sudden onset. More common in young horses.	Spinal ataxia, varying degrees of weakness and proprioceptive deficits. Recumbency. Radiographic lesions present occasionally. CSF may contain red blood cells.	Anti-inflammatory drugs. Rest.
Rye grass staggers	Intoxication by lolitrems produced by *Acremonium lolii* growing on perennial rye grass. Outbreaks of disease in horses on affected pasture.	Ataxia, stiff gait, tremor, hypersensitivity, recumbency. No histologic lesions.	Remove source of toxin. Rapid recovery without other treatment.
Parasite migration	Sporadic. *Strongylus* sp., *Hypoderma* sp., and filaroids (*Setaria* sp.).	Wide variety of clinical signs. Progressive ataxia. CSF may contain eosinophils.	Ivermectin 200 µg/kg. Antiinflammatory drugs.
Congenital anomalies	Sporadic. Cause spinal cord compression or lack of neural tissue, e.g. spina bifida.	Recumbency, ataxia present at birth.	No treatment.

A 'paced growth' program of slowed growth achieved by nutritional restriction of young horses (foals and weanlings) has been suggested as conservative treatment for immature horses with compressive myelopathy or at high risk of developing the disease.[19]

Surgical fusion of cervical vertebrae is useful in the treatment of mildly to moderately affected horses,[20,21] although because of issues of safety of future riders there are concerns by some authorities about the advisability of this treatment.

CONTROL

Control measures are not usually employed, although insuring an appropriate diet and growth rate of at-risk animals would be prudent. Because of the possible inherited nature of the disease, a corrective breeding program may be advisable.

STRINGHALT

Stringhalt is an involuntary, exaggerated flexion of the hock during walking. It can affect one or both hindlimbs. Classic

stringhalt occurs sporadically, is usually unilateral, and is usually irreversible without surgical intervention. Stringhalt can also occur secondarily to injury to the dorsal metatarsus.[1]

A clinically identical disease, Australian stringhalt, occurs in outbreaks in Australia, New Zealand, California, Japan, and Chile.[2,3] The outbreaks tend to occur in late summer or autumn and are related to drought conditions or overgrazing of pasture with consequent ingestion of plants that would otherwise not be eaten.[4] Outbreaks in Australia, California, and Virginia are related to the ingestion of *Hypochoeris radicata* (flatweed, cats ear).[4–8] Other plants suspected to play a role in the etiology include *Taraxacum officinale* (dandelion), *Arctotheca calendula* (capeweed) or *Malva parviflora* (mallow) but good evidence of the role of any of these plants is lacking.

The abnormal movement is only elicited when the horse begins to move forward. The characteristic movement occurs in mildly affected horses when they are backed or turned. Most cases are manifested by a flexion of the hock that can be violent enough for the horse to kick itself in the abdomen. The hoof is held in this position for a moment and then stamped hard on the ground. If both hind legs are affected progress is very slow and difficult and the horses often use a 'bunny hopping' gait. In the most severe cases the horse is unable to rise without assistance. The horse's general health is unaffected although it may be difficult for it to graze. Some cases have other signs of neurologic disease such as stiffness of the forelimbs or respiratory distress due to laryngeal paralysis. Many affected horses have unilateral (usually left) laryngeal hemiplegia evident on endoscopic examination of the larynx. Electromyographic examination reveals markedly abnormal activity including prolonged insertion activity, fibrillation potentials, and positive waves at rest and enhanced EMG activity in the right lateral digital extensor muscle on muscle contraction consistent with denervation. The changes are most severe in the long digital extensor muscle.[6] Most horses recover without treatment, although complete recovery might not occur for over 1 year.[2,5]

There are no characteristic abnormalities in a complete blood count or serum biochemical profile. Pathological findings are restricted to a peripheral neuropathy in the tibial, superficial peroneal and medial plantar nerves and in the left and right recurrent laryngeal nerves.[9,10] Lesions in affected muscles are consistent with denervation atrophy and fiber type grouping.

The signs of the disease are characteristic. Differential diagnosis of the disease involving one leg is ossifying myopathy of the semimembranosus and semitendinosus muscles. Lead toxicosis can induce similar signs in horses.

Treatment with phenytoin (15 mg/kg orally daily for 14 days) effected some improvement but the signs recurred within 1 or 2 days after treatment was discontinued.[11] Myotenectomy of the lateral digital extensor muscle and tendon is reported to provide immediate relief in affected horses, even in those horses with severe bilateral disease.[12] However, recovery is spontaneous in most cases and there might only be a need for surgery in the most severely affected horses. Control involves the prevention of overgrazing of pastures, particularly during droughts.

OVINE 'KANGAROO GAIT'

Synopsis

Etiology Not known
Epidemiology Seasonal occurrence involving only adult female sheep that are lactating, or in some cases, pregnant. Spontaneous recovery following cessation of lactation.
Clinical findings Bilateral forelimb locomotor disorder
Lesions Axonal degeneration of the radial nerve followed by regeneration.
Treatment Supportive
Control None recognized

ETIOLOGY

A neuropathy of unknown cause.

EPIDEMIOLOGY

Occurrence

This condition is recorded in New Zealand and the United Kingdom and is manifest with acute onset of bilateral radial nerve paralysis followed by spontaneous recovery.

Risk factors

It occurs only in adult ewes with an onset in late pregnancy or early lactation.[1–5] Spontaneous recovery occurs following cessation of lactation[1–3] but also occasionally while ewes are still nursing lambs.[4] Average annual cumulative incidence varies between flocks but is less that 1%.[5]

In the areas of northern England and southern Scotland the condition is significantly more common in upland and lowland flocks than in those hill grazing. Stocking density is higher in affected flocks than that in non-affected flocks. Onset occurs while on pasture between March and June with a separate smaller peak in October. This seasonal occurrence could be a reflection the parturition status of flocks or an effect of seasonal influences.[5]

PATHOGENESIS

Clinical signs can be attributed to the generalized polyneuropathy affecting principally the radial nerves. Subsequent to the axonal degeneration a remyelination of the radial nerve occurs, explaining the clinical recovery. Bilateral compression of the radial nerves appears to be the cause but there is no indication of how such an injury can occur.[3]

CLINICAL FINDINGS

The name comes from the gait exhibited by affected ewes which are unable to move their forefeet except in a synchronized bounding action. There is bilateral forelimb paresis, a palpable loss of muscle bulk in the forelimbs, and some cases also have proprioceptive deficits. The hind limbs are normal. Affected ewes lie down more frequently and may graze on their knees but continue to eat and effectively suckle their lambs.

CLINICAL PATHOLOGY

There are no consistent abnormalities in haematology, blood biochemistry, or trace element analysis of affected sheep.[4]

NECROPSY FINDINGS

There is axonal degeneration of the myelinated fibers of the radial nerve fibers and regeneration in recovering cases.[1–3] Ventral root gangliopathy and neuronal degeneration within the spinal cord is reported[1–3] but may not be evident in all cases.[4]

DIFFERENTIAL DIAGNOSIS

Foot rot or foot abscess involving the front feet can have the same grazing behaviour but there is no problem in differentiation when the limbs and feet are examined.

Hypocalcemia in sheep occurs in late pregnancy or during lactation and in the developing stages there is incoordination and muscle weakness. However there is rapid progression to complete muscular paresis and a dramatic response to treatment.

Spinal abscess or fracture.

TREATMENT

Without the knowledge of etiology there is no specific treatment. Easy access to food and water should be provided.

EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a recently recognized **neurodegenerative disease** of horses in the US and Canada, with a small number of cases being recorded in Europe and South America. The disease affects horses of all breeds, with Quarter horses most commonly affected, and the incidence of the disease increases with age.[1] Horses older than 2 years of age are affected. The disease is associated with stabling and lack of access to pasture, and the risk of the disease increases with decreasing serum vitamin E concentration.[2,3] The etiology of the disease is unknown but is suspected to be due to oxidative injury to neurons subsequent to vitamin E deficiency.[3] The clinical signs are attributable to degeneration of motor neurons in the ventral horns of the spinal cord, with subsequent peripheral nerve degeneration and widespread neurogenic muscle atrophy.

The onset of clinical signs is usually gradual but in a small proportion of affected horses the first sign is an acute onset of profound muscle weakness. Chronically affected horses have weight loss in spite of a normal or increased appetite, pronounced trembling and fasciculation of antigravity muscles, increased recumbency, and a short-strided gait; they often assume a posture with all feet under the body and a low head carriage, and frequently shift weight – all signs attributable to muscle weakness.[4] The tail head is elevated in a large proportion of severely affected horses, likely a result of atrophy of the *sacrocaudalis dorsalis medialis* muscle. Retinal examination often reveals accumulation of lipofuscin-like pigment in the tapetal fundus.[5] Electromyography, under either general or regional anesthesia, is a useful diagnostic aid.[6,7] Characteristic findings include spontaneous fibrillation potentials and trains of positive sharp waves. The prognosis is poor and most affected horses do not return to normal function and are destroyed, although the disease stabilizes in some cases that can then live for a number of years after diagnosis.

There is often a mild increase in serum creatine kinase activity. Horses with equine motor neuron disease have abnormal oral and intravenous glucose tolerance tests characterized by peak glucose concentrations that are lower than expected.[8] The lower peak plasma glucose concentration is attributable to a 3x greater rate of glucose metabolism (removal from blood) in affected horses compared to normal horses.[9] There is also evidence that horses with equine motor neuron disease are more sensitive to insulin than are normal horses.[9] Affected horses often have serum vitamin E concentrations that are below the reference range (<1.0–2.0 μg/dL, <1.0–2.0 μmol/L).[3] Horses with equine motor neuron disease have higher spinal cord copper concentrations than do normal horses, but the diagnostic or clinical significance of this observation is unclear.[10] Examination of cerebrospinal fluid is not useful in arriving at a diagnosis.

Examination of muscle from horses with equine motor neuron disease reveals a coordinated shift from characteristics of slow muscle to those of fast twitch muscle including contractile and metabolic functions of muscle.[11] There is a lower percentage of myosin heavy chain type 1 fibers, higher percentages of hybrid IIAX and IIX fibers, atrophy of all fibers, and reduced oxidative capacity, increased glycolytic capacity, and diminished intramuscular glycogen concentrations, among other changes, in affected horses compared to normal horses.[11]

Diagnostic confirmation can be achieved by examination of a biopsy of the *sacrocaudalis dorsalis medialis* muscle or the spinal accessory nerve.[7,12] The *sacrocaudalis dorsalis medialis* muscle is preferred because that muscle is predominantly composed of type 1 fibers and is severely affected by the disease.

Necropsy examination reveals moderate to severe diffuse muscle atrophy. Predominant histologic findings at necropsy examination include degeneration of neurons in ventral horns at all levels of the spinal cord.[13] Muscle atrophy is evident as angular fibers, with predominantly type 1 fibers, or a combination of type 1 and type 2 fibers, affected.[10,11] There is accumulation of lipofuschin in the fundus and in capillary endothelium of the nervous tissue.

Treatment consists of administration of vitamin E, although the efficacy of this treatment has not been determined. Administration of lyophilized, water soluble D-α-tocopherol is apparently superior to administration of the DL-α-tocopherol acetate in increasing concentrations of vitamin E in blood of horses. The usual dose is 4 iu of D-α-tocopherol per kg body weight orally once daily. Control measures should insure that horses have adequate access to pasture or are supplemented with good quality forage and/or vitamin E.

CRUSHED TAIL HEAD SYNDROME IN CATTLE

The crushed tail head syndrome is a recently recognized neuromusculoskeletal disease of dairy cattle which has occurred in the US and UK.[1–3] It occurs most commonly in housed lactating dairy cattle in mid-lactation and that have calved 60 days or more previously. The onset is sudden and characterized clinically by hindlimb weakness, prolonged recumbency in alleyways, but still able to stand. The hindlimbs are drawn forward under the abdomen. Walking is awkward because of hindlimb weakness or pain and affected animals walk with a still rolling gait. Knuckling of the fetlocks and hock joints are characteristic. There is flaccid paralysis of the tail and defecation and urination are not usually affected. During urination and defecation the tail is not lifted and becomes covered with feces and wet with urine. The anal reflex is commonly diminished. There may be some evidence of traumatic injury to the sacral area of the vertebral column with either visible abnormal alignment of the sacral area on movement by the animal or if the animal is rocked from side to side. In other cases, there is no external evidence of trauma or misalignment of the sacrum. No other clinical abnormalities have been observed; appetite is normal, vital signs are normal, and rumen function and the feces are normal in amount and character.

The cause is unknown. In some cases, estrus activity was observed a few days before the onset of signs which suggests that affected animals were mounted by others in the herd causing injury to the tail head and sacrum. It is suggested that traumatic injury to the sacral nerves is the cause of the paresis.

Most cases respond spontaneously and recover within a few weeks. Some reports describe the successful use of long-acting corticosteroids[1] but there insufficient clinical information available to make any useful recommendation.

POLYNEURITIS EQUI (EQUINE CAUDA EQUINA SYNDROME)

Polyneuritis equi (formerly cauda equina neuritis) is a demyelinating, inflammatory disease of peripheral nerves of adult horses. The **etiology** of the disease is unknown although infectious (adenovirus, equine herpesvirus type 1), immune (autoimmune disease), and toxic etiologies have been suggested, without conclusive substantiation. Adenovirus was isolate from 2 of 3 horses with the disease, but this observation has not been repeated and it appears unlikely at this time that adenovirus is the cause of polyneuritis equi.[1] Equine herpesvirus-1 is not consistently isolated from affected horses.[2]

The disease occurs in adult horses in Europe and North America but has not been reported from the Southern Hemisphere. The disease is usually sporadic with single animals on a farm or in a stable affected. However, outbreaks of the disease can affect multiple horses from the same farm over a number of years.

The **pathogenesis** of the disease involves nonsuppurative inflammation of the extradural nerves and demyelination of peripheral nerves. Initial inflammation of the nerves causes hyperesthesia which is followed by loss of sensation as nerves are demyelinated. Both motor and sensory nerves are affected, with subsequent weakness, paresis, muscle atrophy, urinary and fecal retention and incontinence, and gait abnormalities.

The **acute disease** is evident as abrupt onset of hyperesthesia of the perineum and tail head, and perhaps the face, evident as avoidance of touching, and chewing or rubbing of the tail. The hyperesthesia progresses to hypalgesia or anesthesia of the affected regions.

The disease usually has a more **insidious onset** with loss of sensation and function occurring over days to weeks. The most common presentation is that of cauda equina syndrome with bilaterally symmetrical signs of posterior weakness, tail paralysis, fecal and urinary incontinence and retention, and atrophy of the gluteal muscles. Tail tone is decreased or absent and the tail is easily raised by the examiner. The anus is usually atonic and dilated. There are signs of urinary incontinence with urine scalding of the escutcheon and hind legs. Rectal examination reveals fecal retention and a distended bladder that is readily expressed. Male horses can have prolapse of the penis with maintained sensation in the prepuce – a finding consistent with the separate innervation of these anatomic regions. Affected horses can also have ataxia of the hind limbs, but this is always combined with signs of cauda equina disease.

Signs of **cranial nerve dysfunction** occur as part of the disease, but not in all cases. Cranial nerve dysfunction can be symmetrical, but is usually asymmetric. Nerves prominently involved in the genesis of clinical signs are the trigeminal (cranial nerve V), facial (CN VII), and hypoglossal nerve (CN XII), although all cranial nerves can be affected to some extent. Involvement of the cranial nerves is evident as facial paralysis (CN VII), weakness of the tongue (CN XII), and loss of sensation in the skin of the face (CN V). There can be loss of movement of the pinnae (CN VII) and head tilt (CNVIII). Laryngeal paralysis can be present (CN X). The buccal branches of CN VII can be enlarged and palpable over the masseter muscles ventral to the facial crest.

Electromyography is consistent with denervation with prolonged insertion potentials, positive sharp waves, and fibrillation.

Not all clinical signs occur in all horses and, depending on the stage and severity of the disease, some animals can have loss of sensation as the only abnormality, especially during the early stages of the disease.

The disease is inexorably progressive, the prognosis for life is hopeless, and the course of the disease is usually less than 3 months.[3]

Clinical pathologic abnormalities are not diagnostic. There is sometimes a mild neutrophilic leukocytosis and hypergammaglobulinemia. Serum vitamin E concentrations are usually normal. Analysis of cerebrospinal fluid demonstrates mild mononuclear pleocytosis and increased protein concentrations, but these changes are not diagnostic of the disease. Horses with polyneuritis equi have antibodies to P2 myelin protein in serum, but the diagnostic value of this test has not been determined.[4]

Necropsy findings are definitive for the disease. Gross findings include thickening of the epidural nerve roots that is most severe in the cauda equina. The bladder and rectum can be distended. There can be evidence of fecal and urine scalding and self-trauma of the perineum. There can be thickening of the facial nerves. Microscopic changes are characterized by a granulomatous inflammation of the extradural nerves although radiculoganglioneuritis and myelitis can also occur. There is loss of axons with demyelination and signs of remyelination. The inflammatory cells are initially lymphocytes, plasma cells, and macrophages. As the inflammation becomes more severe or chronic there is extensive proliferation of fibroblasts and fibrocytes in addition to infiltration of lymphocytes and macrophages.[2] There is axonal degeneration with proliferation of the perineurium. The chronic inflammatory changes result in loss of peripheral neural architecture. Lesions are present in many regions of the spinal cord, but are most severe in the sacral division and cauda equina.[2] Lysosomal accumulations are present in the semilunar, geniculate, and sympathetic chains and granulomatous lesions in the celiaco-mesenteric ganglion.[5] Lesions of the cranial nerves similarly involve infiltration with lymphocytes and histiocytes, and the inflammation can extend to the terminal branches of the nerves.[3]

The **diagnosis** of polyneuritis equi is based on the presence of clinical signs of the disease, rule out of other diseases causing similar clinical signs, and necropsy examination. Diseases with manifestations similar to polyneuritis equi include:

- Equine herpesvirus-1 myeloencephalopathy
- Migrating parasites (Table 36.3)
- Sorghum–Sudan grass neuropathy
- Equine protozoal myeloencephalitis
- Rye grass staggers (*Acremonium lolii*)
- Dourine
- Trauma to the sacral vertebral column
- Abscess or neoplasia involving the sacral or caudal lumbar vertebral column
- Meningitis
- Intentional alcohol sclerosis of tail head nerves in Quarter horses.

There is no definitive **treatment** for polyneuritis equi. Administration of anti-inflammatory agents, including corticosteroids, appears to be without sustained benefit. Supportive care includes evacuation of the rectum and bladder and maintenance of hydration and provision of adequate nutrition. Feeding a diet that softens feces, or administration of fecal softeners or lubricants can be beneficial. Bethanacol (0.05 to 0.1 mg/kg q8–12 hours, orally) might increase bladder tone. Topical administration of petroleum jelly or similar products can protect the skin of the perineum and escutcheon from fecal and urine scalding.

HEAD SHAKING IN HORSES

Headshaking by horses is a perplexing and troubling syndrome for which there is often no readily identifiable cause or treatment. The disorder is characterized by repeated, sudden shaking or tossing of the head.

ETIOLOGY

The etiology is complex and often unclear and conditions associated with head shaking include:[1,2]

- Ear mites
- Otitis interna/externa
- Ophthalmic disease (uveitis)
- *Trombicularis autumnalis* (chiggers) infestation of the muzzle
- Guttural pouch disease (mycosis)
- Stylohyoid arthropathy
- Osteitis of the petrous temporal bone
- Dental disease (wolf teeth, ulceration, periodontal disease, periapical abscess)
- Behavioral abnormalities
- Trigeminal neuralgia
- Optic neuritis
- Photic head shaking (optic-trigeminal summation)
- Neck pain
- Rhinitis or sinusitis
- Ethmoidal disease including hematoma
- Infraorbital neuritis
- Excessive neck flexion by rider
- Equine protozoal myeloencephalitis
- Ill-fitting tack including bit and bridle
- Obstructive airway disease (heaves, laryngeal hemiplegia, epiglottic cysts, etc.).

Most cases of the disease are idiopathic despite intensive investigation of affected horses.[1] Photic head shaking is a common cause of the disease.[3] Most cases have some seasonal distribution, though the reason for this is undetermined. Trigeminal neuralgia is considered an important cause of the disease.[3]

EPIDEMIOLOGY

The epidemiology of the disease is not well defined. The syndrome occurs in horses throughout the world.[4] The syndrome is sporadic, usually affects only one horse on a farm, and does not occur as outbreaks. The syndrome has a seasonal occurrence in approximately 60% of horses with the majority first demonstrating head shaking, or being most affected, during spring and summer.[4,5] Head shaking is worst on sunny days and less severe on cloudy days, in approximately 60% of horses.[5] Seventy five percent and 80% of affected horses have less severe signs at night or when ridden indoors, respectively.[5]

Affected horses are usually mature adults with onset of head shaking at 7–9 years of age in over one-half of cases,[4,5] although signs can occur in horses as young as 1 year. The disease is reported twice as often in geldings as in mares.[4,5] There is an apparent predisposition to the disease in Thoroughbred horses[4] but this is not consistently reported.[5] Most affected horses are used for general riding, although this might represent an age effect because the syndrome tends to occur in older horses which are not used for racing.[5] There is no apparent association of temperament and risk of head shaking.

PATHOGENESIS

The pathogenesis of headshaking depends on the cause, but is assumed to involve the trigeminal nerve in most cases because of its role in sensory function of the nose and nasal mucosa.[2] Headshaking is related to exposure to bright light in some animals, a condition referred to as photic or optic-trigeminal summation because of its similarity to a syndrome in people. Trigeminal neuralgia is believed to cause acute, sharp, and intense pain in the face. Although this cannot be definitively diagnosed in horses, its presence is inferred from the horse's behavior and response to analgesia of the infraorbital or posterior ethmoidal nerves.

CLINICAL FINDINGS

The **clinical signs** of head shaking are unmistakable. Movements of the head are sudden and apparently spontaneous and involve lateral, dorsal, ventral, or rotatory movement of the nose usually during exercise. Horses rarely have the behavior only at rest, with most being affected both at rest and during exercise and about 10% exhibiting signs only during exercise.[4,5] The action often resembles that of a horse trying to dislodge something from its nose. Approximately 90% of horses have vertical movement of the head (as if flipping the nose).[5] The headshaking can be so severe as to cause lateral, dorsal, or ventral flexion of the neck to the level of the caudal cervical vertebrae, although more commonly on the rostral one-third of the neck is involved, if it is involved at all. Some horses rub their nose on objects, the ground, or their front limbs, sometimes during exercise. Affected horses often snort or sneeze. There can be twitching of the facial muscles and flipping of the upper lip. The movements are sudden and at times appear to catch the horse by surprise. The frequency and/or severity of movements are usually increased during exercise. Severely affected horses can stumble and fall if headshaking occurs during exercise, rendering the horse unsafe to ride.

A grading system to classify the severity of signs is[1]:

0. No signs of head shaking
1. Intermittent and mild clinical signs. Facial muscle twitching. Rideable.
2. Moderate clinical signs. Definable conditions under which head shaking occurs. Rideable with some difficulty.
3. Rideable to unpleasant to do so. Difficult to control.
4. Unrideable and uncontrollable.
5. Dangerous with bizarre behavior patterns.

This system might be useful for assessing response to therapy and concisely describing the severity of the signs.

Ancillary testing involves radiography of the skull; endoscopic examination of both nostrils and ethmoidal regions, nasopharynx, larynx, and guttural pouches; otoscopic examination of the external auditory canal and tympanic membrane (difficult to achieve in a conscious horse, a small endoscope is necessary); desensitization of the infraorbital and posterior ethmoidal nerves; biopsy of the nasal mucosa (in horses with suspected rhinitis); radiographic examination of the neck; and therapeutic trials including application of contact lenses or masks, or administration of medications (see 'Treatment').

CLINICAL PATHOLOGY

There are no characteristic hematologic or serum biochemical abnormalities.

NECROPSY FINDINGS

There are no characteristic findings on necropsy, apart from those of any underlying disease. Evidence of lesions in the trigeminal nerve is lacking.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from the stereotypic weaving that occurs during stabling and not during exercise.[6]

TREATMENT

The principles of treatment include relief of specific underlying diseases, removal of management or environmental conditions that cause head shaking, and administration of medications.

If underlying conditions are detected, such as ear mites, dental disease, and others listed under 'Etiology', then these conditions should be treated effectively. Effective treatment of these conditions will alleviate head shaking, if in fact the condition was the cause of the disease. However, most horses with head shaking have seasonal or photic disease and treatment is more difficult. A survey of owners of 254 horses with head shaking revealed that

only 129 horses had been treated by a veterinarian and, of those, only 6% had complete resolution of head shaking, whereas 72% had no response to treatment.[7] Other treatments used were on the advice of lay 'back specialists', homeopathy, alternative therapies or face or head masks. Success rates for these interventions varied between 6 and 27%, with the most success obtained by use of a nose net (27%).[7] Nose nets provided better control of signs than did face or eye masks. These figures on the success of treatment illustrate the refractory, and therefore frustrating, nature of the disease.

Fitting of **nose masks** alleviates or lessens head shaking in some horses.[7,8] The design of the nose mask does not appear to be important at least in regard to whether it covers the entire rostral face or just the nostrils.[8] The nose masks were most effective for treatment of up-and-down head shaking, but not for side-to-side or rubbing behavior.[8]

Blue tinted **contact lenses** have been suggested for use in horses with photic head shaking.[9] Others have not found this intervention useful.[4]

Sclerosis of the infraorbital or posterior ethmoidal nerves is performed in those horses that have reduced or eliminated head shaking after injection of local anesthetic into the infraorbital foramen or around the posterior ethmoidal nerve.[1] Sclerosis is achieved by injection of 5 mL of 10% phenol in oil.[1] Care must be taken to ensure that the phenol is deposited only around the nerve. The procedure should be done under general anesthesia.

Cyproheptadine (0.3 mg/kg, orally q12 hourly) improved head shaking in 43 of 61 horses, based on owner reported efficacy.[4] Responses were usually observed within 1 week of the start of therapy. Others have not replicated this success[1] but found that the combination of **carbamazepine** (4 mg/kg orally q6–8 hours) and cyproheptadine improved clinical signs in 7 horses within 3 to 4 days of starting treatment.[1]

Acupuncture and **chiropractic** manipulation appear to be minimally effective.[4,7]

Prevention of exposure to bright light is an obvious recommendation, but not practical for most horse owners.

CONTROL

There are no recognized measures for preventing development of the disease.

CONGENITAL NECROTIZING ENCEPHALOPATHY IN LAMBS

This condition is reported as the most common diagnosis of neurological disease in lambs under 7 days of age by VLA diagnostic laboratories in the north of England and is defined by its pathology.[1] Affected flocks have single or multiple cases with up to 10% morbidity in lambs of a flock. Cases have all come from ewes carrying multiple fetuses. There is variation in the clinical manifestations between sibling lambs. The most severely affected may be stillborn. Less severely affected lambs are born weak, are small, maybe unable to rise or show ataxia and head tremor. Some lambs survive but may have residual signs of cerebellar dysfunction. The common lesion is superficial cerebrocortical neuronal necrosis. A significant proportion also has necrosis of the Purkinje cells in the cerebellum and leucoencephalopathy of the thalamus and brainstem. It is possible that this syndrome reflects hypoglycemia consequent to negative energy balance in late pregnancy.

Diseases characterized by involvement of the musculoskeletal system

HYENA DISEASE OF CATTLE

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena.[1,2] The cause is unknown but excessive intake of vitamins A and D may be contributing factors.

In some naturally occurring cases in yearlings from one large dairy herd approximately 1% of calves were affected annually. Affected calves had received vitamins A and D_3 immediately after birth, and from birth to weaning received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement.[2] The mean daily intake of vitamin A from birth to 6 weeks of age was approximately 80 000 iu and 6300 iu of vitamin D_3, and progressively less vitamin A and D_3 was fed from 6 weeks until weaning at 3 months. The National Research Council recommendations for daily vitamin intake are 2100 iu of vitamin A at birth, increasing to 6360 iu at 2 months and 330 iu of D_3 increasing to 990 iu over the same period.[2] Experimentally, the IM injection of vitamins A and D (2 000 000 iu and 300 000 iu, respectively) on the first day after birth followed by 30 000 iu/kg BW added to the milk replacer daily results in gross lesions in the proximal tibial growth plates in 3 weeks.[3] Excessive vitamin A and vitamin D_3 administration to young calves can cause hyena disease by suppression of the activity of differentiation and proliferation in chondrocytes and osteoblasts.[4,5] The administration of excessive amounts of vitamins A, D_3, and E to Holstein sucking calves can cause hyena disease characterized clinically by severe emaciation, generalized alopecia, dome-like cranial deformation, and high mortality.[6]

There is premature closure of the growth plates of the long bones resulting in a marked dissimilarity in growth and development between the forequarters and the hindquarters, the latter being comparatively underdeveloped. This gives the animal the classic contours of the hyena and this resemblance is heightened by a crest of thick, stiff bristles along the back in the midline. An aggressive attitude also develops. Affected calves are normal at birth and only develop the abnormality at 5–6 months of age. There is no apparent abnormality of sex hormones. The femur and tibia are shorter in affected than in normal animals. There are accompanying difficulties of locomotion with a tendency to fall sideways, and to frequently adopt a position of lateral recumbency. The gait is described as 'bunny-hopping'.

German Simmental, Charolais, Black Pied, German Holstein-Friesian, and German Red Pied cattle have been involved. Genetic analysis appears to indicate that the disease is inherited as a simple recessive with incomplete penetrance but this is obviously not so in some herds.

The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibias, and femurs reveal focal to almost complete closure of the physes and physes subjected to compression are affected more than those subjected to tension.[2]

ASYMMETRIC HINDQUARTER SYNDROME OF PIGS

This condition was first reported in Germany[1] and Belgium[2] and was recognized in the UK in 1968 and reported later.[3] In these cases perineurial fibrosis was a feature and it was thought that the condition resulted from either a neurogenic atrophy or a periarticular fibrosis extending to the peripheral nerves. There is variable asymmetry of the hindquarters which is generally evident during the early grower period and obvious by 80 kg liveweight stage. An asymmetrical distribution of subcutaneous fat is also noted and possibly skin dimpling.[4,5] The muscle most frequently affected was the *M. semimembranous*, followed by the *M. semitendinosus*, *M. biceps femoris*, *M. adductor femoris*, and *M. gracilis*. The muscles show changes that can be described as myofibre degeneration, interstitial fibrosis, and dystrophic changes. Several breeds, including Landrace, Large White, and Hampshire have been found affected but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition.[2] The mechanism of inheritance studied from test matings is not simple.[3] Whatever the cause, there is a marked reduction in the number of muscle fibres. Both sexes may be involved and the condition may involve either hindlimb. Despite a marked reduction in muscle mass there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss.[6] In the only cases recorded from outside Europe a group of 7 Australian pigs were examined in detail[7] and in one of these the affected *M. semitendinosus* weighed only 41% of the normal unaffected one. Perineural fibrosis and myopathy have been observed in some cases but have not been found consistently.[6]

SPLAYLEG SYNDROME IN NEWBORN PIGS

This syndrom is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term as this hypoplasia occurs in many normal pigs and may be a normal feature of post-natal muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.[1]

ETIOLOGY

The etiology is unknown, but based on epidemiological evidence it is multifactorial.[1] The current hypothesis is that the disease is caused by an interaction of genetic and non-genetic factors, a polygenic mode or expression of many genes without dominance.

The studies of Czech workers[2,3] have suggested that the pathomorphology of the condition resembles that of glucocorticoid induced myopathy in man and animals.[4] Dexamethasone given to minisows from the first to the last days of pregnancy produced in newborn piglets a disorder characterized by the splayleg syndrome with retardation of both muscle growth and myofibillogenesis.[3,5] It has also been experimentally produced following the administration of pyrimethamine.[6]

EPIDEMIOLOGY

The prevalence of the disease in the UK is 0–4% and the morbidity in affected herds varies from 2 to 27%. The case fatality rate is approximately 50% and is due to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease.[1] On most farms the disease affects both male and female piglets. In a recent retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times more in males than females and the birth weight of splayleg piglets tended to be subnormal.[7] The environmental factors which have been associated with some outbreaks include slippery floors, a dietary choline deficiency and the ingestion of **Fusarium toxin** by pregnant sows. Choline deficiency is unlikely to be a factor[8] and none of the other factors have been substantiated as etiological factors or epidemiological determinants.[1]

PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia[9,10] but this is also a feature of many muscles in normal pigs. There are simply too few maturing type 1 fibrils in the muscles, particularly of the foreleg, lumbar epaxial group and the hind limb to carry weight. The *Mm semitendinosus* appears to be the worst affected muscle. However, because myofibrillar hypoplasia may also be present in normal unaffected littermates[1] it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia.[11] In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes.[12] The extramyofibrillar space was also filled with glycogen in splayleg pigs.[13] In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs but the extramyofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies which indicate a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia but there was an increased accumulation of glycogen especially within the large extramyofibrillar spaces in comparison with the normal pigs.[14] These authors also found an anomalous distribution of glucose-6-phosphatase in splaylegged muscles in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles this enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build up.[14] Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic-type) and qualitative (dystrophic-type) insufficiencies in affected pigs which represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery which occurs.

CLINICAL FINDINGS

Larger litters may be more affected possibly because these tend to be born earlier. The clinical signs are usually obvious in 2–3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, and their hindlimbs are splayed sideways or forwards and the animals are resting in sternal recumbency. Sometimes the fore limbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of

nourishment. Affected piglets are normal in other respects and have a normal appetite and will suck the sow if placed near a teat. In the experimental induction[5] there was hypoplasia but there were no clinical signs, which is further evidence for suggestions[15] that the condition has a threshold for clinical signs and has strong maternal influences.

TREATMENT

Treatment can be successful.[16] If the pigs are able to suck or if they are fed artificially for 2–4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by taping or loosely tying together the hindlimbs for a period of up to 1 week. The method of loose tying of the hindlimbs consists of a figure-of-eight bandage (2.5 cm wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a non-slip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

CONTROL

Whether or not to cull the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a less superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent upon the selection of stress-resistant boars and sows.

Concurrent disease should be controlled as producers will tell you that after a period of PRRS infection they had a higher percentage of splayleg piglets. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

DEGENERATIVE JOINT DISEASE (OSTEOCHONDROSIS, OSTEOARTHROSIS, EPIPHYSEOLYSIS AND APOPHYSIOLYSIS, LEG WEAKNESS IN PIGS)

Leg weakness in pigs is a very loose term which includes a wide variety of conditions and is best discarded. In Finland 15% of gilts are culled due to leg weakness.[1] Degenerative joint disease would be a much better general term to describe the lameness of young rapidly growing pigs affected with a non-infectious joint disease which includes osteochondrosis (OC), epiphyseolysis, and degenerative osteoarthrosis (OA). The disease is characterized by varying degrees of intermittent but progressive lameness in rapidly growing pigs from 4 to 8 months of age, and pathologically by the presence of OA and OC. The disease is of major economic importance because of the high culling rate of breeding age swine.

Synopsis

Etiology The cause is unknown.
Epidemiology Occurs in majority of breeds of rapidly growing pigs and young breeding females and males. Lesions are commonly present at slaughter. May be related to nutrition and rapid growth rate, genetic predisposition, and type of flooring but no reliable correlations.
Signs These may be no clinical findings or possibly lameness and inability to breed.
Clinical pathology Radiographic evidence of osteochondrosis.
Lesions Osteochondrotic lesions of varying degrees of development, severity and healing.
Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
Other causes of lameness include:

- Polyarthritis due to infectious causes
- Laminitis
- Nutritional osteodystrophy due to calcium, phosphorus, and vitamin D imbalance
- Hypovitaminosis A causing hindlimb paresis.

Treatment None.
Control Uncertain. Select breeding stock with sound legs and gait.

ETIOLOGY

The cause of the articular abnormalities is not known. The etiology and factors underlying these syndromes are poorly defined, partly because of the difficulty of definitive clinical examination of affected pigs and the frequent lack of apparent significant pathological changes in necropsy examination of mild cases. There are no specific associations between degenerative joint disease and infectious diseases.[2]

EPIDEMIOLOGY

Occurrence

Recently, a study of 9411 newborn piglets showed that 9.8% were treated for lameness. For parity 3 sows, the level had risen to 11.4%, but by parities 4–7 only 8% were treated. The treatments were in pigs of less than 3 weeks of age in 73% of the cases. Litters with 12 or more pigs had the highest incidences of lameness.[3] Osteoarthritic changes are strongly associated with osteochondrotic changes in the humeral and femoral condyles.[4] Osteochondrosis has been recorded as early as 1 day of age so the lesions may be congenital. There may be some degree of change in up to 85% of pigs.

The intensification of the swine industry has required that pigs grow rapidly and with high feed efficiency. Under such intensified conditions, rapidly growing pigs develop lesions of the bones and joints, especially the femur. Most pigs near market weight have varying degrees of osteochondrosis (OC). Except for severe lesions, which usually occur in a relatively small proportion of the total population examined, the lesions seen at slaughter often have no detrimental effect on growth rate of pigs up to market weight. An advanced degree of OC however, can result in severe degenerative joint disease and lameness in breeding stock. It is not associated with adventitious bursitis.[5]

The disease occurs in both male and female pigs and the incidence of lame pigs can be as high as 20–30%. It is a particular problem in gilt and boar testing stations where it may necessitate slaughter of affected animals before the testing period is complete. The lesions develop

most commonly in growing pigs, particularly boars from 20 to 30 weeks of age, raised in confinement. The onset occurs when pigs are between 4 and 8 months of age which coincides with a period of maximal growth rate. The peak period of clinical manifestation is from the late grower stage until 18 months of age, although the effect of OA may carry through to the adult period. Extensive multicentric degenerative joint disease in adult sows and boars can cause severe lameness which often warrants euthanasia.[6] However, sows ranging in age from 1.5 to 3.0 years and culled for impaired reproductive performance, with no history of lameness may have lesions of the femoral condylar surface.[7]

Risk factors

Numerous risk factors contribute to the disease. They include nutrition and rate of growth, genetic, and breed predisposition, sex, type and quality of floor, and exercise and confinement. The pig carries 53–51% of its weight on the fore limbs and 46–48% on the hind but the weight supported on the hind is higher at 90 and 105 kg body weight.[8] In a study of gilts and sows in Denmark about 12% of gilts showed stiff locomotion but at some point 53% of gilts had at some time showed the same sign. Buck-kneed forelegs, upright pasterns, legs turned out wide, standing under position, and swinging hindquarters were associated with stiff locomotion or lameness. Weak pasterns on the hind feet were associated with stiff locomotion and lameness.[9] Weak pasterns on hindlegs and splayed digits on forelegs were associated with brisk movement (freedom from locomotor problems). The following leg weakness signs at the gilt stage were found to have a significant effect on the longevity of the sows: buck-kneed forelegs, swinging hindquarters, and standing under position on the hind legs.

Nutrition and rate of growth. The disease is associated with rapid early growth,[10] but it does not appear to be related to protein, vitamins A and D or calcium and phosphorus imbalance in the ration.[11] Maximal mineralization of bones is not necessary to prevent leg weakness. Only almost complete absence of calcium and phosphorus causes lameness. Disturbances of the Ca:P ratio below 0.5 or over 3.0 are necessary to produce lameness. Recently, it has been suggested that long-term acidosis may be associated, as bone is not formed as phosphorus is removed from the bone. In this context the acidification of pig diets has been suggested as a contributory cause. It has also been shown that the presence of deformed forelimbs is not associated with low levels of vitamin C in plasma.[12] Rapid growth, especially during the early period, was thought to have a significant influence on the occurrence[13] and there is also some breed variation in susceptibility. However, in some feeding trials of pigs from weaning to slaughter weight there was no direct effect of rapid growth rate on the incidence and severity of OC. In other feeding trials, average daily gain of gilts was an important factor in the severity of lesions of OC. Decreasing the rate of gain by restricting energy intake appeared to decrease the prevalence and severity of OC when gilts were slaughtered at 110 kg.[14] However it was shown that when pigs were fed waste food, and grew more slowly, they had an increased prevalence and score for OC when compared with pigs fed a commercial feed concentrate.[15] Decreasing the concentration of protein in the diet of gilts from 16 to 12% resulted in less longitudinal bone growth but did not decrease the incidence of OC.[16,17] A simple association between growth rate and the incidence or severity of joint lesions has not been consistently demonstrated and a reduction in growth rate of pigs does not control the disease. A significant favourable association between leg action and daily gain has been noted.[18] There has also been speculation that growth hormone could influence the development of lesions of OC by exerting a direct effect on differentiation and colonization of epiphyseal chondrocytes. There is no consistent relationship between the incidence of osteochondrosis and selection of pigs for lean tissue growth rate.[19] It may be simply that more feed means more growth which makes stress on developing cartilage worse and therefore predisposes to OC.

Genetic and breed predisposition. It has been proposed for many years that selection of pigs for increased growth rate resulted in a concomitant increase in the incidence and severity of musculoskeletal disease. Genetic studies indicate that the heritabilities of leg weakness are low to moderate (0.1–0.3).[20] A more recent study suggested from 0.01 to 0.42 for leg weakness and OC and that both are associated with production traits (lean% and backfat thickness).[14] Genetic analysis of the incidence of OC and leg weakness in the Swedish pig progeny testing scheme revealed a low to moderate heritability. Genetic control of leg weakness has been achieved by various researchers and thus inheritance is probably an important risk factor for this disease complex. The genetics of leg weakness have been described in Finnish Large White and Landrace populations.[21] Meaty breeds are worst affected including the Duroc and the Dutch and Swedish Landrace.

Osteochondrosis also occurs in crossbred Wild boar-Yorkshire pigs with a genetically decreased growth rate, raised under the same conditions as finishing pigs.[22] The distribution and extent of OC was similar to that of purebred Swedish Yorkshire pigs. This suggests that it is not limited to rapidly growing pigs. Synovial bursae at the hock joints were higher in Large White pigs with straight or bowed hind legs and in Landrace with sickle shaped hind legs.[23] There are significant breed differences in the peri-articular and meniscal ossifications seen on X-ray.[24] Recently, the quantitative trait loci for locomotion and osteochondrosis-related traits have been identified in Large White x Meishan pigs.[25] Correlations between breeding values for longevity and for OC were low but significant, and in a favourable direction. Higher OC scores were associated with a higher risk of being culled.[26] It has been seen in wild boar in Slovenia.[27]

Sex. The differences in the incidence and severity of OC between the sexes of different breeds has also been analyzed. The degree of leg weakness and OC of one sex in a breed can neither be translated to the other sex within that breed nor to the same sex of another breed.

Type of floor. Insecure footing because of unfavorable floor surfaces and the presence of foot lesions may change the posture of the animal and cause local overloading of certain joints. The effect of the quality of floor has been examined and there is no clear evidence that hardness of floor contributes to an increased incidence of leg weakness associated with joint disease. However, the incidence and severity of joint lesions may be related to the duration of confinement in pigs confined individually. Exercise will prevent abnormalities such as bow legs, flexion of the carpus and sickle-legs from impairing the mobility of boars, but does not influence the severity of joint lesion. The milder syndromes of poor movement and lameness associated with defects in leg conformation in the grower stage are not necessarily associated with bone or joint lesions and may regress spontaneously or improve if affected pigs are placed on pasture. However, severe lameness at this age, and that which occurs in replacement stock and young adults is frequently associated with severe bone and joint lesions which may be irreversible. A recent study has looked at type of floor (solid floor plus straw, solid floor no straw, and fully slatted).[28] The slatted floors were worst for leg weakness and the floors with straw best. The different types of floor affected leg weakness and claw disorders differently.

Exercise and confinement. There is some limited evidence that high lean growth rate may predispose toward leg weakness under confinement rearing. Trauma during handling, penning, and transportation may be associated with a relatively high frequency of OC but the evidence is very limited.[29] A high stocking density had an adverse effect on 4 of the leg weakness signs (knock knees, turned out front or hind limbs, standing with the legs under the body).[28] A recent study of housing and treadmill training did not show any adverse effects on leg weakness.[30] It has even been seen in pigs on grass, on deep litter and in wild boar

Economic importance

In Scandinavia, breeding pigs culled because of lameness had a 100% frequency of OC or OA, and up to 40% of boars in a performance test station had osteochondrosis or osteoarthrosis.[6] A conservative estimate suggests that 3% of sows and 10% of boars are culled for unsoundness associated with OC and OA.[6] The hidden costs include a reduced pool for selection of high-performance boars and gilts, the maintenance of pigs which cannot be used for breeding, increased mortality among piglets crushed by lame sows, reduced feed intake and growth rate in lame pigs, and transportation costs of replacement stock.

PATHOGENESIS

The condition has been seen as early as 1 day and with age the lesions develop. The essential lesion is the necrosis of cartilage canals and surrounding cartilage.[31,32] They may be seen to be developing and healing at the same time. In growing animals, the superficial layer of joint cartilage is articular cartilage, and the deeper layer is epiphyseal cartilage which undergoes endochondral ossification as the animal matures. The articular cartilage persists in the mature animal while the epiphyseal cartilage becomes a layer of calcified cartilage and underlying subchondral bone. The cartilage of the physis is known as the growth plate and is involved in metaphyseal growth. The normal growth plate cartilage has a well-ordered structure with the chondrocytes of the proliferative and hypertrophic regions arranged into columns.

Osteochondrosis is a generalized disease in which there are focal areas of failure of endochondral ossification in the physeal (metaphyseal growth) and epiphyseal growth cartilages. The underlying defect may be an abnormality of the chondrocytes which do not undergo normal hypertrophic ossification. They accumulate rough endoplasmic reticulum, lipid droplets and mitochondria. The surrounding matrix contains deposits of electron-dense material which may prevent normal vascularization and therefore ossification. The hypertrophic region is disorganized and greatly extended compared to normal tissue.[33] The matrix surrounding the clustered chondrocytes is altered compared to that in normal cartilage.[34] The primary abnormality is an increased thickness of the joint cartilages combined with degenerative changes which result in infoldings and erosion of articular cartilages. Defects of the growth plates (physes) result in short deformed bones.

Pathologically, severe clinical cases are characterized by osteochondrosis and secondary degenerative joint disease especially involving the medial aspects of the larger joints, epiphyseolysis and lumbar intervertebral disc degeneration and spondylosis. Osteochondrosis has been used to encompass lesions involving the physes and the articular epiphyseal complexes. However, because of morphological changes that have been observed in growing pigs, dyschondroplasia is now the preferred term to be used generically and then qualified by the location and nature of the morphological description since the causes may be different.

Osteochondrosis occurs commonly in growing pigs at predilection sites of the medical condyle of the humerus and femur, the epiphyseal plates of the distal ulna and the femoral head and the intervertebral joints. The 6th–8th costochondral junctions may also be affected. It may heal spontaneously or it may progress to *osteochondritis dissecans* and OA. Its progression in either direction is influenced by local loading and by joint stability which depends upon joint shape and muscle and ligamentous support. The age-related changes and OC in the articular and epiphyseal cartilage have been described.[35] The cartilage increases with age up to 5 weeks and then begins to decrease in thickness. Deleterious influences such as defects in conformation, heavy muscling with skeletal immaturity, muscular weakness resulting from myofibrillar hypoplasia, myopathies or lack of exercise, inadequate flooring or even simple trauma may adversely affect this progression and lead to severe skeletal change.

Porcine synovial fluid contains both hyaluronic acid and chondroitin sulfate and the chondroitin sulfate-to-hyaluronic acid ratio is not influenced by relatively advanced stages of osteochondrosis. Treatment of lame boars with glycosaminoglycan polysulfate improves leg soundness score and results in an increase in the hyaluronic acid concentration of the cubitus joint synovial fluid, and an increase in the proportion of aggregated proteoglycans in the articular cartilage of the medial femoral condyle. It is suggested that the hyaluronic acid accounts for most of the viscosity of synovial fluid and for efficient lubrication of the joint.

Well-established lesions typical of OC associated with the physes can be found in young pigs between 25 and 30 days of age.[6] The earliest change associated with a dyschondroplasia of the physis is a focus of persistent hypertrophied chondrocytes which do progress but heal. Lesions associated with physes and articular epiphyseal complexes develop continuously and regress as pigs grow older. Changes in cartilage canal vessels appear to be important in the pathogenesis.[36] There is no evidence that vascular damage is a factor in the pathogenesis of the lesions.

Because foci of dyschondroplastic lesions are associated with physes of pigs between birth and the stage of rapid growth, they could be regarded as part of the usual growth patterns in contemporary commercial swine. However, clinical signs of dyschondroplasias, or degenerative joint disease secondary to dyschondroplasias, usually do not appear until pigs are almost 6 months of age.

Radiological monitoring of lesions

Osteochondrosis can be diagnosed radiologically.[13] Radiologically the lesions were similar in Yorkshire, and Landrace[37] but more severe in the Landrace and similar to the Danish Landrace.

The development of epiphyseal osteochondrosis in pigs from 42 to 147 days of age has been followed radiologically.[38] Osteochondrotic lesions were seen radiologically in the articular-epiphyseal (A–E) complexes of the humeral condyles of 42-day-old pigs and in the femoral condyles at 63 days of age in contrast to earlier reports which indicated that lesions were not visible radiologically until 100 days of age. The osteochondrosis lesions of the A–E complexes develop, become progressive, and subsequently become either stable, regressive, or even more progressive as the pigs grows. This supports the observations that the lesions develop and become progressive and regress as the pigs grow. The humeral medial condyles have more pronounced lesions and are more frequent than the lateral ones.

Radiological monitoring of the development and sequelae of physeal osteochondrosis lesions of the growth plate cartilage and A–E complexes of the fore and hind limbs in young breeding swine found that the majority of distal ulna lesions healed by 18–20 months and some started fusing at 18–21 months. The distal ulna healed without complications in most animals and the most severe lesions healed faster than the mild or moderate ones.[38] In a recent study periarticular ossifications at the elbow joint

were found in the radiographs at a prevalence of 0.9%.[4] Meniscal ossifications were seen as single or multiple foci at the cranial aspect of the joint at a prevalence of 2.6% and had a bilateral occurrence of 20%.[4,39] Meniscal ossifications were associated with hind legs turned out and stiff locomotion in the hind leg and negatively associated with growth rate.

CLINICAL FINDINGS

The syndrome is called leg weakness and varies in severity from locomotor abnormality that results from conformation and leg defects such as narrow lumbar area and broad hips, hyperflexion of the carpus, bowing of the forelimbs and 'knock knees', hyperextension of the phalanges, lateral angulation of the foot and sickle hocks to more severe lameness and, in the extreme, inability to rise and paresis. Nine leg weakness signs were described.[28] The signs listed include buck kneed forelegs, steep hock joints, fore and hind limbs turned out, upright pasterns on the hind legs, stiff locomotion, standing under on the hind limbs, swaying hindquarters, goose stepping hind legs, lameness and tendency to slip,[4] and the four most common signs were buck knees, small inner claws on forefeet, small inner claws on hind feet, and upright pasterns on the hind legs.[4,40]

The clinical syndrome is a locomotor disorder usually involving the hindlimbs. Often the most rapidly growing pigs are lame. The lameness may be acute, intermittent, chronic, progressive, or a combination of these. An insidious onset is common, and pigs are unwilling to move, the stride is shortened, and the limbs are held in partial flexion. The carpal joints may be under extended, the metacarpophalangeal joints are overextended, giving the limb an abnormal S-shaped profile.[6] The pelvic limbs are commonly held straight and the back is slightly arched. In some cases, affected animals will assume a kneeling position with flexed carpal joints and walk on those joints.

Mild cases show stiffness, especially immediately after a period of lying down and lameness. Slowness to rise and a tendency to walk with short steps on tiptoes frequently in association with a marked inward curve of hindlimb motion during forward progression and side-to-side motion of the buttocks is frequently seen. More severely affected pigs sit on their hindquarters and are reluctant to stand. They carry one or both hindlimbs more forward under the body and walk with a short goose-stepping gait. Wasting is not a feature except in severely affected animals and the locomotor disorder may be minor unless exacerbated by physical exertion.

The syndrome is of particular importance in breeding animals where it may interfere with successful mating. Boars may show initial interest in mounting but subsequently slide off the sow or dummy before mating is complete, presumably due to the pain of the limb lesions. In Europe this problem has been called *impotentia coeundi*.

There may be no meaningful association between visual scores for physical soundness in the live animal and the degree of joint damage.[41] Some pigs with severe lesions are not lame and conversely other pigs are severely lame with minor lesions. Epiphyseolysis of the femoral head produces severe unilateral lameness and if bilateral is usually manifest by marked reluctance to rise and severe locomotor disability. Initial signs are frequently deceptively mild and follow physical exertion such as mating, transport, farrowing, or fighting but they progress to severe lameness over a 7–10-day period.

Epiphyseolysis of the tuber ischii (Apophysiolysis) may also occur following physical exertion but is more common in second or third parity sows and is manifest by 'paralysis' with the hindlimbs in forward extension under the body of the sow.[42] These animals 'dog sit', and are unable to rise. In many instances the injury occurs when the animals arrive on the farm or are first mated.

Because of the pain and muscle contraction, it is frequently difficult to determine the site and severity of the lesion by simple clinical examination, and palpation following general anesthesia or radiography may be required for proper clinical assessment. Physical examination should include complete palpation of all limbs for warmth, swelling, and pain. The palpable parts of the pelvis should be examined with particular emphasis on the ischial tuberosities. Passive flexion, extension and rotation of each limb along with auscultation over the joint may reveal evidence of crepitus or a pain response.

While the lesions of the physes and articular epiphyseal complexes are detectable in pigs under 14 days of age they are not detectable radiographically in live animals until the pigs are over 100 days of age. Only 21% of the lesions associated with the physes and 22% of the lesions associated with the articular epiphyseal complexes were detectable in radiographs of bones of live pigs.

Meniscal ossifications were observed as simple or multiple small smooth firm and irregular swellings in the cranial horn of the lateral meniscus.[24] The peri-articular osseus foci were seen as focal firm swellings at the cranio-medial aspect of the elbow joint.[24]

CLINICAL PATHOLOGY

The carpal, elbow, tarsal, and stifle joints can be radiographed for evidence of joint lesions, and the lesions scored according to a system.[38] It is also possible to use ultrasonics for diagnosis.[43]

NECROPSY FINDINGS

The histological, radiological, and angiomicrographical findings of dyschondroplasias of the growth cartilages in crossbred commercial pigs at 1 and 15 days of age have been described. The bone lesions in clinically normal and lame pigs have been described.[44,45] The scapulohumeral, humeroradioulnar, carpal, coxofemoral, femorotibial, and tarsal joints should be examined. Typically, in osteochondrosis, the changes are feathery hypertrophy of villi, focal full-thickness cartilage buckles, ulcers of flaps, and no change in the draining lymph node. Joint mice and synovitis may also be seen. Deformation may take place in the long bones or even fractures. Histologically, osseus trabeculae may be seen with clusters of chondrocytes, and between the trabeculae lined by flat osteoblasts there are adipocytes. The osseous center was formed of mineralized cartilage that blended into more or less fibrous cartilage but towards the joint cavity the meniscal ossifications were covered by hyaline cartilage.[24]

Occasional cases involve the patella in breeding age pigs.[16]

The ultrastructural characteristics of normal epiphyseal cartilage of the articular epiphyseal cartilage complex in growing swine has been examined and found to be different from the articular cartilage and the cartilage of the physis.[46] Histochemical techniques are now used to characterize lesions of osteochondrosis and the lesions associated with articular-epiphyseal cartilage complexes should be considered as different entities.[35] Osteopenic lesions have been described.[47]

DIFFERENTIAL DIAGNOSIS

The syndrome must be differentiated from other diseases which cause lameness and paralysis in growing and young adult pigs which includes: infectious polyarthritis, laminitis, traumatic foot lesions, foot lesions produced by biotin deficiency and footrot, osteodystrophy resulting from calcium, phosphorus and vitamin D imbalance in rations, vitamin A deficiency and viral encephalomyelitis.

TREATMENT

There is no effective treatment. Early cases may recover spontaneously after being placed outside on pasture or housed individually inside on deep straw litter. Recently, it has been suggested that meloxicam at a dosage of 0.4 mg/kg is

efficacious and safe for the treatment of non-infectious locomotor disorders in pigs. Treatment with 2,5-D vitamin D had no effect on the incidence and severity of OC/OA lesions.[48] Animals that are affected with clinical signs should be removed from the herd quickly and, if necessary, should be humanely destroyed as soon as possible.

CONTROL

Because the etiology is unknown, it is not possible to provide specific control measures. The hereditary nature of the disease suggests that the selection of breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. Genetic control of leg weakness has been documented by various researchers.[41] Selection of boars for leg soundness has dramatic effects on the structural soundness of their crossbred progeny and therefore selection of structurally sound replacements must be maintained if leg weakness in market or breeding pigs is to be avoided.[49] Divergent selection for leg soundness in Duroc pigs has been dramatic.[49] Progeny of leg-soundness sires had significantly better measures for all leg traits at 104 kg than did progeny of leg-weakness sires.[35] Differences between the two progeny groups indicated that the realized heritability for front leg soundness exceeded 0.50.[35]

Selection of breeding stock will require careful genetic selection, examination of all pigs which are to be retained for breeding, necropsy of siblings of affected pigs and of the same gender, to identify genetic lines of pigs which have a low incidence of lesions. A recent study showed that the increase in wild boar alleles in crosses with Large White pigs reduced the prevalence of OC.[50] It has been suggested that the selection of pigs based on the joint lesion score could lead to a better leg and joint condition both optically and pathologically.[51] The reduction of growth rate and exercise may help but are not a real method of control. Increase in calcium and phosphorus in the diet also does not help.

SPORADIC LYMPHANGITIS (BIGLEG, WEED)

This is a non-contagious disease of horses characterized by acute fever, lymphangitis and severe swelling of one or both hindlegs – forelimbs are rarely, if ever, affected. The disease commences abruptly with fever (40.5–41°C, 105–106°F), shivering and a rapid pulse rate and respiration. Pain in the acute disease can be severe. There is severe pain on palpation of the affected leg and lameness may be so severe that the horse may refuse to put its foot to the ground. The limb is swollen and hot; the swelling extends from the top of the leg and down to the coronet. There is cording of the lymphatics on the medical aspect of the leg and palpable enlargement of the lymph nodes in some horses. The acute disease resolves into a chronic phase with persistent and variable swelling of the leg, intermittent fever, and variable lameness. Occasionally abscesses develop in the lymph nodes and vessels but usually there is no localization of the infection. There is a tendency for the disease to recur and cause chronic fibrotic thickening of the lower part of the limb extending to the level of the stifle in many horses. Swelling of the leg is often exacerbated by late pregnancy.

Sporadic lymphangitis can be associated with superficial wounds and ulcers on the lower parts of the limbs, but often there are no wounds detected. The disease is thought to develop as a lymphangitis and, potentially, lymphadenitis of the deep inguinal nodes as a result of these wounds. The affected lymph nodes and swelling of the limb obstruct lymphatic and venous drainage causing lymphatic obstruction, edema and, in some cases, cellulitis.[1] Ultrasonographic examination reveals distended lymph vessels that contain fluid that is not echogenic. Ultrasound guided aspiration of this fluid yeilds fluid with a low total protein concentration and mild neutrophilia (high proportion of the cells present in the fluid are neutrophils, although the absolute count is usually less than 1.0×10^9 cells/L. Culture of the fluid is recommended, and *Actinobacillus* sp. have been obtained. The clinical significance of results of culture of the fluid is unknown, but results could be used to guide choice of antibiotics. Radiographic examination is usually unremarkable apart from demonstrating the soft tissue swelling. Affected horses, in both the acute and chronic stages, have a mild neutrophilia and hyperfibrinogenemia.

Acutely affected horses should be treated aggressively. The principles of treatment are control of the presumed infection, reduction of inflammation, and reduction of swelling. Penicillin or other antimicrobials should be administered parenterally to control the infection. Non-steroidal antiinflammatory drugs (phenylbutazone, flunixin meglumine, carprofen, or similar) should be administered to

control the inflammation and provide pain relief. The limb should be hosed with cold water once to twice daily to reduce heat and provided with gently massage therapy. Manual massage of the limb might be beneficial. Supportive, compressive bandaging of the limb can reduce the swelling. The horse should be exercised as much as is practical and humane.

Horses with chronic disease should be treated with prolonged courses of antimicrobials (penicillin, sulfonamide-trimethoprim combinations, enrofloxacin, or rifampin in combination with sulfonamides-trimethoprim), non-steroidal drugs, and local therapy. Acute exacerbations can be managed by administration of dexamethasone (40 μg/kg orally or parenterally, once daily for 5 days, and then gradually tapering). This dose is not abortifacient in pregnant mares. Exercise and supportive bandaging are important in minimizing the swelling. The chronic disease requires prolonged and intermittent therapy, often for the rest of the horse's life.

Prevention of the disease necessitates prompt and careful treatment of all wounds of the lower limbs. Provision of daily exercise, restriction of the diet during prolonged rest periods and dry standing in the stable also help to prevent the disease.

LAMINITIS OF HORSES

Synopsis

Etiology Degeneration of the sensitive laminae of the hoof.
Epidemiology Disease involving single animals. As a sequela to severe systemic disease including colic, diarrhea, metritis, and grain engorgement. Horses or ponies at pasture. Horses worked on hard surfaces. Obese horses and ponies. Horses with unilateral lameness may develop laminitis in the contralateral, supporting limb.
Clinical signs Lameness, ranging from mild to sufficiently severe to cause the horse to be recumbent, involving both front feet, and occasionally all four feet.
Clinical pathology None characteristic of the disease.
Diagnostic confirmation Physical examination. Radiography.
Treatment There is no single effective treatment. Non-steroidal anti-inflammatory drugs, dimethyl sulfoxide, vasodilatory agents, anticoagulants, frog and sole support, and corrective hoof trimming and shoeing are all used with variable success.
Control Prophylaxis for acute, severe diseases. Aggressive treatment of metritis, colic and diarrhea. Prevent unrestricted access to feeds rich in soluble carbohydrates. Maintain optimal body condition.

ETIOLOGY

Laminitis is caused by **acute degeneration of the sensitive primary and secondary laminae** of the hoof. The cause of this degeneration is unknown although a number of theories have been propounded and are summarized under 'Pathogenesis'. Situations that are associated with increased risk of laminitis include access to lush pasture (suspected as the cause in 46% of field cases), grain overload (7%), retained placenta (2%), and colic or diarrhea (3%).[1] Ingestion of large quantities of soluble carbohydrate, such as grain, bread, calf feed, or exposure to shavings of black walnut (*Juglans nigra*) causes laminitis.

EPIDEMIOLOGY

Occurrence

Single sporadic cases are the rule for **horses** in which the disease is usually related to individual risk factors such as obesity, systemic illness, or lameness. An estimated 13% of horse operations in the United States have a horse with laminitis at any one time, and laminitis accounts for 7.5 to 15.7% of all lameness in horses.[1] Laminitis accounts for up to 40% of hoof problems in horses, depending on the use of the horse.[1] Approximately 5% of horses with laminitis die or are euthanized.[1] Among cases occurring in the field (as opposed to veterinary hospitals) approximately 74% recover and become sound, with 8% improving but continuing to be lame.[1] However, approximately 10% of horses that developed laminitis had a permanent change in their primary use as a result of having developed laminitis.[1]

Risk factors

Animal risk factors

With the exception of overweight ponies and horses with systemic disease, there are only a few identified innate factors that predispose individual horses to the development of laminitis:

- Any association between the disease and age, sex or breed is weak, again, with the exception of ponies.[2] There is no difference in risk among horses used for pleasure riding, showing, breeding, racing, or farm and ranch work.[1]
- The disease is more common in the United States during spring and summer (1.3% in spring and 0.4% in winter in the central US).[1]
- The disease is very uncommon in foals and horses < 8 months of age, and then increases in frequency with increasing age such that horses >20 years of age have an incidence of the disease roughly 3 times that of horses between 5 and 20 years of age.[1]
- **Overweight ponies** appear to be most susceptible and the disease occurs four times as commonly in them as in other classes of horse.[3] Fat ponies at pasture and getting little exercise commonly develop the chronic form of the disease.
- Laminitis is common in horses with tumors of the intermediate lobe of the pituitary (pars intermedia dysfunction, equine Cushing's disease).

Trauma and other physical factors such as excessive work on hard surfaces, increased weight bearing on one limb, and persistent pawing contribute to the development of the disease in horses. Standing for periods of days during transport may predispose to laminitis. For horses that are severely lame, and not bearing weight in the affected limb, the risk of developing laminitis in the contralateral limb is related solely to the duration of lameness and not to body weight.[4]

Laminitis is associated with many **systemic illnesses** of horses. Horses with illness attributable to colic, diarrhea, pleuropneumonia, and metritis are prone to develop laminitis. **Potomac horse fever** (equine neorickettsiosis) is frequently a cause of laminitis in horses and laminitis is the major cause of mortality from this disease. Approximately 28% of horses with **anterior enteritis** (duodenitis/proximal jejunitis) develop laminitis, usually within 2 days of developing enteritis.[5] There are anecdotal reports that suggest that administration of **corticosteroids** (dexamethasone, triamcinolone) causes or exacerbates laminitis, but this association has not been proved. Laminitis is common in horses that engorge on grain or similar feeds containing a high concentration of soluble carbohydrates. Ingestion of large quantities of lush pasture has been anecdotally associated with increased risk of laminitis, especially amongst ponies. It is believed that the presence of a high concentration of soluble carbohydrates fructans in the grass is responsible for the increased risk of laminitis.[6] Fructans are metabolized in the large colon and may mimic the situation after ingestion of a large quantity of soluble carbohydrate.

Importance

Death is unusual, but the severe lameness may cause a great deal of inconvenience and affected horses may develop permanent deformities of the feet. Many have to be euthanized.

PATHOGENESIS

The basic lesion of laminitis is the separation of the sensitive laminae of the third phalanx from the interdigitating laminae lining the internal surface of the hoof, so that the third phalanx drops through the hoof and comes to rest on the sole. Exactly

what the mechanism is that links the risk factors listed above to the laminar degeneration, the basis of the separation, is unknown. Briefly, the theories are:

- Ischemia of the laminae with subsequent necrosis. Proposed causes of ischemia include vasoconstriction, development of arterio-venous shunts, interstitial edema, and presence of microthrombi in digital vessels.[7–13] Ischemia due to microthrombus formation is considered an unlikely cause of laminitis.[7,8] However, there is evidence from experimental laminitis that changes in circulating concentrations of vasoactive amines or contractile activity of vessels in the hoof might contribute to ischemia. Alternatively, increases in capillary filtration pressure, resulting from venoconstriction, might cause edema and increased interstitial pressure with subsequent ischemia of the laminae.[13] It is plausible that there is a combination of these mechanisms, beginning with digital venoconstriction and ending in arteriovenous shunting and development of microthrombi [14] There is evidence in horses with gastrointestinal disease treated by emergency celiotomy that endotoxemia after surgery is associated with lower digital blood flow and higher concentrations of endothelin-1, providing evidence for a role of decreased laminar blood flow in the pathogenesis of the natural disease.[15]
- Inflammation, with subsequent degeneration of sensitive laminae.[16–18]
- Enzymatic digestion of laminae by matrix metalloproteins (MMPs) induced by circulating factors including products of *Streptococcus bovis* infection.[19,20]
- Abnormalities in local (hoof) metabolism of corticosteroid resulting in increased glucocorticoid activity in lamellar tissues [21]

There is evidence of each of these mechanisms. The evidence is often based on experimental models of laminitis and the findings differ somewhat with respect to the model used and markedly with the stage of disease studied. More recent studies, focusing on the developmental stage before clinical signs are apparent, have identified evidence of inflammation associated with a marked increase in expression of cycloxygenase-2, an enzyme critical in the metabolism of vasoactive and inflammatory prostaglandins and inhibited by non-steroidal antiflammatory drugs.[16]

It is speculated that a **pain-hypertension-vasoconstriction** cycle develops in horses with acute laminitis. The pain associated with the laminar degeneration causes release of vasoconstrictor substances such as the catecholamines, angiotensin II, and vasopressin. These substances then cause peripheral vasoconstriction with a subsequent reduction in blood flow to the foot, and systemic hypertension.

The common thread is that degeneration of the sensitive laminae. Loss of the connection between the third phalanx and hoof allows the third phalanx to **rotate** within the hoof capsule, likely in response to the torque applied by the deep digital flexor tendon, and to displace ventrally (**sink**) within the hoof as a result of weight transmitted through the third phalanx; or there may be a combination of these changes. Rotation of the third phalanx causes the sole to be pushed downward or'dropped', and the point of the toe of the third phalanx may actually penetrate the sole. Serum accumulates in the space created by degeneration of the laminae and displacement of the third phalanx and there is breakdown of the white line.

Many of the inciting causes of laminitis are diseases that may be associated with **endotoxemia**, and in experimental models endotoxin was detectable in the blood of horses that developed laminitis, suggesting that endotoxin may contribute to the development of the disease. However, infusions of endotoxin do not cause laminitis, although endotoxin does impair endothelium-dependent relaxation and augments adrenergic contraction of palmar digital arteries.[22]

The disease occurs in 3 distinct phases: (1) a developmental stage in which lesions are detectable in the sensitive laminae but during which there are no clinical signs; (2) the acute phase from the development of the first clinical signs through to rapid resolution or to rotation or ventral displacement of the third phalanx; and (3) the chronic stage evidenced by rotation of the third phalanx with or without ventral displacement and characterized by variable but persistent pain.

CLINICAL FINDINGS

The disease presents as both an acute disease and as a chronic disease.The severity of the acute disease varies considerably from very mild with rapid (5–7 days) recovery, to severe with progression to the chronic, refractory stage.

The acute disease develops rapidly; apparently normal horses can founder within hours. Signs of the disease are entirely attributable to pain in the feet. All hooves may be affected, but more commonly the fore feet are affected and the hind feet are spared. The disease is rarely unilateral except in cases in which the disease develops because of severe lameness in the contralateral limb or repeated pawing. Mild, or early, disease is apparent as a resistance to movement and repetitive and frequent shifting of weight from one foot to the other. There is a characteristic shuffling gait.

More severe disease is apparent as refusal to move or to lift a hoof. At this stage the horse wears an expression of great **anxiety**, accompanied by **muscle fasciculation, sweating**, a marked increase in heart rate to as high as 75/min, rapid, shallow respiration, and a moderate elevation of temperature. There is a **characteristic posture** with all four feet being placed forward of their normal position, the head held low, and the back arched. There is usually a great deal of difficulty in getting the animal to move and when it does so the gait is shuffling and stumbling and the animal evidences great pain when the foot is put to the ground. The act of lying down is accomplished only with difficulty, often after a number of preliminary attempts. There is also difficulty in getting the animals to rise and some horses may be recumbent for long periods. It is not unusual for horses to lie flat on their sides. In occasional cases the separation of the wall from the laminae is acute and the hoof is shed. There may be exudation of serum at the coronet and this is considered a sign of impending sloughing of the hoof and a poor prognosis.

The diagnostic signs in laminitis include pain on palpation around the coronet and a marked withdrawal response when hoof testers are applied to the hoof. The **intensity of the pulse** in the palmar digital artery, palpable over the abaxial aspects of the proximal sesamoid, of affected feet is markedly increased over normal. In horses in which the third phalanx is displaced distally (sinks), a concavity may be palpable at the coronary band. Infiltration of the palmar digital nerves at the level of the proximal sesamoid with local anesthetic agents provides marked, but not complete, relief.

In the chronic stages of the disease there is separation of the wall from the sensitive laminae and a consequent dropping of the sole. The hoof wall spreads and develops marked horizontal ridges, and the slope of the anterior surface of the wall becomes accentuated and concave. Horses with chronic or refractory laminitis may continue to feel much pain, lose weight, and develop **decubitus ulcers** over pressure points because of prolonged recumbency. Loss of integrity of the sole and disruption of the white line may

allow **infection** to develop in the degenerate laminae. The infection may spread to involve the pedal bone, causing a septic pedal osteomyelitis. The lameness may abate but the animal becomes lame easily with exercise and may suffer repeated, mild attacks of laminitis.

Radiographic examination of the feet may not reveal, initially and in mild cases, changes in the position of the pedal bone. Radiographs of more severe or advanced cases will demonstrate **rotation of the pedal bone** within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone may fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. **Displacement of the pedal bone** toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the pedal bone. Chronic or refractory cases may have **osteopenia** of the pedal bone with proliferation of bone at the toe.

Prognosis. The **radiographic examination** provides information of **prognostic value**. Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5°, whereas horses that can no longer perform as athletes usually have more than 11.5° of rotation.[23] However, there is considerable overlap between groups and these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the proximal limit of the extensor process of the distal phalanx (the 'founder' distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx.[24] While values for these measures vary among breeds and with the size of the horse, most normal horses will have a 'founder' distance of 4.1 ± 2.2 (standard deviation) mm and a wall thickness of 16.3 ± 2.4 mm.[24]

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

The disease is not usually fatal but if a necropsy examination is carried out on an acute case, the stomach usually contains excessive amounts of grain, which has a pasty, mealy consistency and an odor suggestive of putrefaction of protein. Retained placenta and metritis may be present in postparturient laminitis in mares. No other reliable gross findings are visible, although the vessels of the sensitive laminae of the digital cushion may appear engorged if the cut surface of the hoof is examined.

In subacute and chronic cases the diagnosis can easily be confirmed by gross examination of sagittal sections of the foot. This permits assessment of the horny, soft, and osseous components of the foot. In some cases the degree of rotation of P3 results in perforation of sole.

Histological examination is required only in acute cases and confirmation of the diagnosis in such instances demands that the foot be cut into slab sections and fixed shortly after the death of the animal, before even moderate autolysis can ensue. Microscopically, the sequence of acute changes in experimentally induced laminitis begins with the loss of some of the keratogenic structures of the epidermal laminae. This is followed by vascular engorgement, edema and some necrosis of laminar tissues.

DIFFERENTIAL DIAGNOSIS

Horses

Rhabdomyolysis, tetanus, colic, and spinal ataxia may all mimic the immobility and pain of laminitis, but there is no pain in the feet in these diseases, and other distinguishing characteristics are apparent on careful clinical examination.

TREATMENT

Acute laminitis is an emergency and treatment should be started without delay, as early and aggressive therapy might enhance the chances of recovery.

The adage 'where facts are few experts are many' (Donald R. Gannon) applies well to the treatment of laminitis. There are no well-designed studies of the treatment of naturally occurring laminitis and thus the choice of treatment is based on personal experience, extrapolation from our imperfect understanding of the pathogenesis of the disease, the availability of certain drugs, and current fashion. In general, the treatments can be grouped into several classes, based on the intended intervention. These are:

- **Removal of the causative agent or treatment of the inciting disease**
- **Pain relief and minimization of inflammation**
- **Vasodilation of blood vessels in the foot**
- **Prevention of formation of microthrombi in dermal capillaries**
- **Prevention of rotation or distal displacement of the pedal bone**
- **Promotion of keratinization and hoof growth.**

The efficacy of administration of analgesic, anti-inflammatory, anticoagulant and vasodilatory drugs, local therapy such as ice baths of the hoof or having the horse stand in cold water, and mechanical support of the hoof has never been demonstrated in appropriate clinical trials.

Treatment of inciting disease

The inciting disease should be treated aggressively and every attempt made to remove any causative agent. Horses with traumatic laminitis should be rested and housed in stalls that are well bedded with sand or soft shavings. Horses suspected of having a tumor of the intermediate lobe of the pituitary gland should have the diagnosis confirmed and appropriate therapy instituted.

Analgesics and anti-inflammatory drugs

A mainstay of the treatment of both acute and chronic laminitis is the use of non-steroidal anti-inflammatory drugs (NSAIDs). Apart from the obvious humane requirement of providing pain relief, the use of NSAIDs is speculated to be beneficial by breaking the pain-hypertension-peripheral vasoconstriction cycle that may be important in the pathogenesis of laminitis. Furthermore, recent evidence suggesting that inflammation mediated by COX-2 plays a role in the developmental phase of laminitis supports the early and aggressive use of NSAIDs.[16] **Phenylbutazone**, at doses of 2.2–4.4 mg/kg intravenously or orally every 12–24 hours, is an effective analgesic in cases of mild to moderate laminitis. Higher doses (6.6 mg/kg every 12–24 hours) may be required in severe cases. However, the potential for phenylbutazone toxicosis, evident as colic, gastrointestinal ulceration, nephrosis, hypoproteinemia, leukopenia, and hyponatremia, is dose related and high doses of phenylbutazone should only be used for at most several days and only in severely painful horses. **Flunixin meglumine** (1.1 mg/kg, IM or IV every 8–12 hours) and **ketoprofen** (2.2 mg/kg, IM every 12–24 hours) are also effective analgesics.[25] Their concurrent use with phenylbutazone may enhance pain relief but also increases the risk of NSAID toxicosis. The use of aspirin is dealt with under Anticoagulants.

Dimethyl sulfoxide (DMSO), a putative anti-inflammatory drug that is also reputed to scavenge free radicals, has been used in the treatment of acute laminitis, again without clear demonstration of its efficacy. DMSO is administered at a rate of 1 g/kg, intravenously as a 10% solution in isotonic sodium chloride. The treatment can be repeated daily for several days.

Narcotic analgesics such as butorphanol and meperidine (pethidine) provide some pain relief but in general are not as effective as the NSAIDs. Similarly, α-2 agonists such as **xylazine and detomidine** provide only brief respite from the pain, and may be contraindicated because of the vasoconstriction associated with their use.

Local analgesia of the foot with agents such as lidocaine or bupivacaine provides marked pain relief. However, analgesia is usually only brief, depending on the agent used, and has the disadvantage of causing the horse to bear more weight on the affected limbs. Local analgesia may be useful in facilitating relocation of the horse, hoof trimming, corrective shoeing, or application of sole and frog support but not as a routine treatment.

Because of suspicion that **corticosteroids** induce or exacerbate laminitis, at this time their use is contraindicated in the treatment of laminitis.

Vasodilatory drugs

Vasodilatory drugs are used on the premise that vasoconstriction is an important mechanism underlying the development or progression of acute laminitis. Several classes of drugs have been used including α-adrenergic antagonists such as phenoxybenzamine and phentolamine, drugs with multiple mechanisms of action such as acetylpromazine and isoxuprine, and nitric oxide donors including glyceryl trinitrate (nitroglycerine) and L-arginine.[26] None of the vasodilatory drugs should be used in horses with compromised cardiovascular function or dehydration.

Phenoxybenzamine and phentolamine are not readily available and have limited use. Phenoxybenzamine causes sedation. **Acetylpromazine** is a potent vasodilator, principally because of its α-adrenergic antagonist activity, that is currently used frequently in the treatment of acute laminitis. Acetylpromazine increases blood flow to the digit, but its effect on nutritive flow to the laminae is unknown, as is the case for all the vasodilators.[27] The effect of acetylpromazine persists for approximately 90 minutes after intravenous administration.[27] Acetylpromazine can be administered at dose rates ranging from 0.01 to 0.05 mg/kg, IM, every 6–12 hours. Sedation may be considerable at the higher doses and/or with more frequent administration. **Isoxuprine** is a combined α-antagonist and β-agonist that increases blood flow to the leg but not to the foot in normal horses.[27,28] It has been used at doses of 1–1.5 mg/kg orally every 12 hours. Pentoxyfilline (4.4 mg/kg orally q8 hours) does not increase digital blood flow in normal horses.[27]

Application of **glyceryl trinitrate**, a nitric oxide donor, to the palmar digital arteries of affected horses has been reported to increase or not affect blood flow to the dorsal hoof wall.[29,30] However, the effect of these substances on the course of the disease is unknown. In spontaneous cases of acute laminitis glyceryl trinitrate has been applied to the skin over both palmar digital arteries of affected feet at a dose of 15–30 mg per artery, once daily. However, because of lack of evidence of efficacy and the potential for systemic hypotension secondary to systemic absorption of the drug, its use is no longer recommended.

Anticoagulants

Anticoagulant drugs are administered to prevent the development of microthrombi within the hoof. **Aspirin and heparin** are commonly used. Aspirin is a very poor analgesic in horses but is used because it reduces platelet aggregation in normal horses by blocking formation of thromboxane A_2. However, thromboxane may not be an important cause of platelet aggregation in horses.[31] Aspirin is administered at a dose of 10 mg/kg orally every 48 hours.

Heparin in sufficient doses prolongs blood clotting, provided that there is adequate antithrombin III in the patient's blood. Heparin has been reported to prevent or to have no effect on the development of laminitis in horses with anterior enteritis or colic, respectively. Heparin can be administered at 40 to 80 iμ/kg IV or subcutaneously every 8–12 hours for 3–5 days. Anemia may develop during heparin administration, but resolves rapidly when administration of the drug is stopped.

Mechanical support

Mechanical support to provide pain relief and in an attempt to prevent rotation or distal displacement of the pedal bone is an important part of the care of horses with acute laminitis.

Support of the frog and/or sole can be achieved using packing material such as dental acrylic or firm plastic that is molded to conform to the shape of the sole. Some clinicians prefer to use **wedge pads** to elevate the heel and reduce tension in the deep digital flexor tendon with the aim of preventing rotation of the pedal bone.

Housing the horse on sand or other soft bedding is frequently recommended.

Corrective shoeing of horses with chronic laminitis is widely practiced and there are proponents of a wide variety of shoe types (fullered egg-bar, heart bar, glue-on shoes). Appropriate hoof care, which might include shoeing, is important in managing horses with chronic laminitis. Interestingly, there was not a difference among shoe types in efficacy for pain relief in horses with chronic laminitis.[32]

Promotion of healing

Methionine has been given to both acute and chronic laminitis cases on the known requirement for methionine in the chondroitin complex of collagen. There is some rationale for the treatment but it seems more appropriate as a supportive than as a principal treatment. The recommended oral dose rate is 10 g/day for 3 days followed by 5 g/day for 10 days.

Antibiotics may be indicated to prevent secondary infection of the degenerate laminae.

Rest is important in the convalescent phase. Horses with no rotation or sinking of the pedal bone should be given 21 days of rest after resolution of the clinical signs. Return to work should be gradual. Horses that develop rotation or sinking of the pedal bone should be monitored both by physical examination and radiographic examination. It will be many months before horses with even mild rotation can be returned to work. Horses with severe rotation will likely never resume active work, although they may become pasture sound.

Summary of treatment of acute laminitis

Depending on the cause, treatment of acute laminitis should include:

- The administration of non-steroidal anti-inflammatory drugs (preferably phenylbutazone)
- Vasodilators (acetylpromazine)
- Support of the frog and/or sole
- Housing on sand or similar soft bedding
- The inciting disease should be treated aggressively
- After the acute phase has passed, likely in 5–7 days, attention should be given to trimming the hoof and corrective shoeing.

Chronic, refractory laminitis

The **prognosis** for chronic or refractory laminitis (laminitis of more than 1 week's duration) is poor (see above for the use of radiography to determine prognosis). Treatment includes NSAIDs for pain relief, corrective shoeing (egg bar or heart bar shoes), and trimming of the hoof (shortening the toe or complete removal of the dorsal hoof wall). **Tenotomy** of the deep digital flexor may provide temporary relief but does not affect the long-term prognosis.

CONTROL

The disease is not readily subject to control because of its sporadic nature. Heavily fed or fat horses should be given some exercise when not working; if possible, horses in transit should be removed from the transport vehicle, given light exercise and rested for several hours at the end of each day; retained placenta in mares should

be treated promptly. Heavy carbohydrate feeding should be avoided. Susceptible ponies should have limited access to pasture either by limiting the time that they spend at pasture or by application of a grazing muzzle.

LAMINITIS IN RUMINANTS AND PIGS

Synopsis

Etiology Degeneration of the sensitive laminae of the hoof.
Epidemiology
Cattle: An endemic disease of some herds of high producing dairy cattle, and in feedlots. Associated with ruminal acidosis, either clinical or subclinical.
Clinical signs
Cattle: Inapparent to severe lameness, most common in the hind feet. Predisposition to other infectious or traumatic diseases of the foot.
Clinical pathology None characteristic of the disease.
Diagnostic confirmation Physical examination. Radiography.
Treatment
Cattle: Non-steroidal anti-inflammatory drugs. Corrective hoof care.
Control
Cattle: Dietary control to prevent ruminal acidosis. Correction of housing and flooring problems.

ETIOLOGY

Laminitis is caused by acute degeneration of the sensitive primary and secondary laminae of the hoof. The cause of this degeneration is unknown. The disease is less well characterized than that of horses and several conditions are often classified as laminitis.

EPIDEMIOLOGY

Occurrence

In **cattle** the disease may occur as clusters in herds and on farms where a predisposition appears to be inherited or where access to large quantities of soluble carbohydrate are available such as for high producing dairy cows or feedlot cattle. On farms of high-producing dairy cattle the prevalence may be as high as 78%.[1] The disease is also reported in calves and first calf heifers.

Risk factors

Cattle and sheep

Subclinical laminitis that predisposes to the development of other diseases of the hoof occurs in calves and first calf heifers and is common in intensively fed feedlot cattle.[2] Laminitis, conditioned by the inheritance of an autosomal recessive gene, is recorded in Jersey heifers.[3] There may be an association between the disease in feedlot ruminants and **ruminal acidosis**.

Beef cattle being prepared for shows are often grossly overfed on high grain rations and become affected with a chronic form of the disease which markedly affects their gait and may cause permanent foot deformity. The disease occurs in dairy cattle fed improper rations, and especially first calf heifers and cattle of herds attempting to increase milk production[1,4] and it is not uncommon for the disease to present as a herd problem.

Among **dairy cattle** the heifers are usually worst affected and the disease usually develops soon after calving, with more than 50% of cases occurring in the period 30 days before and 30 days after calving. There may be a relationship between being introduced to the herd, with the frequent harassment by dominant cows, when heavily pregnant and when the surface of the yards is rough. Housing may be important including standing in slurry or having to twist and turn in narrow passageways and races, and there is an association between the prevalence of the disease and rough concrete floors.[5,6]

Diet is an important risk factor for development of laminitis in heifers. Diets of wet, fermented grass silage are associated with a greater risk of laminitis than are diets rich in dry unfermented straw and a concentrate.[7] Furthermore, transition from a low net energy diet to a high net energy diet immediately after calving increases the risk of subclinical mastitis in Holstein dairy cows.[8]

The disease is also reported to occur after metritis, retained placenta, mastitis, and mammary edema but the incidence is not usually very high.

Pigs

Laminitis has been recorded in pigs but the disease is difficult to diagnose in this species and many cases secondary to other diseases, e.g. postparturient fever, may be missed. The disease is also recorded when pigs are fed very heavy concentrate diets.

Importance

Subclinical laminitis of dairy cattle predisposes to other hoof disease that may decrease milk production.

PATHOGENESIS

The pathogenesis of laminitis in cattle, sheep, and pigs is unclear, but likely has some similarity to that in horses (see Laminitis in horses). Subclinical laminitis can predispose to white line disease.

CLINICAL FINDINGS

Cattle and sheep

In these species the clinical picture is similar to but less marked than that observed in the horse.

In calves 4–6 months of age, and in heifers, an acute syndrome similar to that seen in the horse has been described. Affected animals lie down much of the time, and are reluctant to rise. When they attempt to rise they remain kneeling for long periods. Their standing posture is with all four feet bunched together and the back is arched; they shift their weight from foot to foot frequently and walk with a shuffling painful gait. The feet are painful when squeezed and later become flattened and enlarged and look as though slippers are being worn. There is severe ventral rotation of the third phalanx.

In adult cows some cases have acute signs, others show only local lesions. These include sole ulcers and patchy changes in the horn including softening, waxy yellow discoloration, and red-brown patches suggestive of previous hemorrhage. The cow is chronically lame.[9]

Young bulls are very susceptible to laminitis and may develop abnormalities

of gait and posture, such as a stilted gait and frequent knuckling of the fetlocks, which may mislead the diagnostician.

Chronic laminitis in adult cows is characterized by a smaller anterior hoof wall-sole angle, down from 558 to 358, a concave anterior wall, and the appearance of horizontal grooves (growth arrest lines) around the entire claw. The sole is usually dropped a little and bruising and sole ulcers may be present. Overgrowth of the sole of the lateral claw may reach the point of creating a false or double sole. The white line is greatly widened and disrupted and stones and other debris may be impacted in it.[10]

Chronic, traumatic laminitis is most common in heifers when they are first introduced into the milking or dry herds. Housing them on concrete and exposing them to frequent confrontations with bossy cows lead to the development of sole hemorrhages and inflammation of the laminae.

Radiographic signs in cattle include rarefaction of the pedal bone, particularly the toe, and the development of osteophytes at the heel and on the pyramidal process.

Pigs

In sows the clinical signs are similar and include arching of the back, bunching of the feet, awkwardness of movement, increased pulsation in the digital arteries and pain when pressure is applied to the feet.

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

Histological findings in the feet of cows affected by laminitis are similar to those in horses.

DIFFERENTIAL DIAGNOSIS

Cattle

White muscle disease, epiphysitis.

TREATMENT

Although similar principles to those used to determine treatment of laminitis in horses are likely to apply to cattle, treatment in cattle is usually limited to administration of NSAID (aspirin 0.3 grains/kg, orally every 12 hours, phenylbutazone 4.4 mg/kg orally every 48 hours or flunixin meglumine 1.0 mg/kg IV every 12 hours). The inciting cause (metritis, ruminal acidosis) should be treated aggressively.

CONTROL

Cattle and lambs which are brought into feedlots should be gradually introduced to grain feeds and a higher forage:grain ratio provided in the feed. Calves should not be fed intensively on grain until they are 14 months old because of the high frequency of internal hoof lesions at the earlier ages. Some protection against laminitis in dairy cattle in intensive units is gained by careful planning of housing cubicles to make them more comfortable and less damaging to the feet, and by providing more straw in the cubicles. Exercise should be provided around calving time. Vaccination with a Gram-negative bacterin-endotoxoid combination vaccine has provided some protection against laminitis induced by grain overload. Dietary supplementation of biotin (20 mg per head per day) improves hoof health of primiparous dairy cows[11] and may be beneficial in reducing the incidence or severity of lameness in a herd. This treatment might not improve objective indicators of hoof health, but it does improve production.[12]

'ACORN' CALVES

A non-inherited condition has been described in the US and Australia which resembles inherited dwarfism.[1] The disease occurs on poor range country and is thought to be due to a maternal nutritional deficiency during the middle trimester of pregnancy. The specific dietary factors involved have not been determined, although supplementary feeding during pregnancy eliminates the condition.

Abnormal osseous development of the head causes it to be either shorter or longer. Shortening of the shafts of the long bones of the limbs is accompanied by bending at the joints, and calves nurse and stand with difficulty. Incoordination, arching of the back and a tendency to bloat, which may cause death, also occur. The dentition is normal. Muscle spasticity, wry neck, circling, falling backwards, and goose-stepping occur rarely.

Most of the calves are born alive and, in badly affected herds, as many as 15% of calves may be affected. The condition derives its name from the common occurrence of acorns in the diet of affected herds, although the acorns are not thought to have any etiological significance.

CONGENITAL JOINT LAXITY AND DWARFISM IN BEEF CALVES (DYSCHONDROPLASIA IN NON-INHERITED CONGENITAL DWARFISM IN BEEF CALVES)

Congenital joint laxity and dwarfism is a skeletal anomaly which has affected beef calves in Canada,[1–3] Australia,[4] and Ireland.[5] The disease has been recognized in beef cattle ranches in north central British Columbia and Alberta, and northwestern Ontario.[1]

ETIOLOGY AND EPIDEMIOLOGY

The etiology is unknown. Epidemiologically, the disease has been associated with feeding clover silage or grass silage without dry feed or grain supplementation to pregnant cows over the winter months.[3] The disease is seen almost exclusively in beef herds where pit silage makes up the bulk of the ration. In an outbreak in a beef herd in Prince Edward Island, Canada, feeding spoiled silage to pregnant cattle may have been a risk factor.[3] An apparent greater incidence in beef herds in the northern part of the UK may be associated with longer periods of winter feeding in the northern part of the country.[6,7] There is no evidence that manganese deficiency is a causative factor.[3,5]

The problem can be eliminated by supplementation of the silage diet with a combination of hay and rolled barley.[2] In one study, calves born to first-calf heifers were 3.2 times more likely to be affected compared to calves born to mature cows.[8] In the Australian report, the pregnant dams had experienced severe nutritional deficiency between 3 and 6 months of gestation.[4]

Controlled feeding trials have supported the epidemiological observations that the disease occurs in calves born to cows fed exclusively grass or clover silage over the winter months.[2] Supplementation of the grass and clover silage diet with hay (2.5–4.5 kg/head per day) and rolled barley (0.75–1.5 kg/head per day) eliminated the problem. Supplementation with grain but no hay reduced the risk of abnormal calves to a lesser degree. The period of gestation during which the fetus is

susceptible to the abnormality ranges from 107 to 230 days. It is suggested that irreversible injury to the fetus occurs by day 180 of gestation.

Prenatal rickets was considered as a possibility in the early stages of the investigations. The overgrowth of chondrocytes and delayed mineralization of the growth plates of affected calves in previous years were similar to those described for neonatal rickets. In addition, the vitamin D concentration of silage may be low and the wavelengths of ultraviolet light necessary for transformation of the provitamin 7-hydroxycalciferol to vitamin D_3 are almost entirely filtered out by the atmosphere during the winter months because of the acute angle of the sun in northern latitudes. In Canada, pregnant beef cows fed exclusively a diet of grass or clover silage during the winter months may have low levels of vitamin D. However, supplementation of pregnant cows with vitamin D_3 during one winter season did not reduce the risk of abnormal calves.

The disease resembles 'acorn calves' which have occurred in California and Australia. One possible hypothesis suggests that the two conditions may share a common pathway.[2] Certain unspecified seasonal and environmental conditions or stressors may convert forage into a teratogenic substance. In areas where acorn calves occur, supplementation feeding of the cows on pasture practically eliminates the problem.

CLINICAL AND PATHOLOGIC FINDINGS

The abnormalities are obvious at birth and characterized clinically by generalized joint laxity, disproportionate dwarfism and, occasionally, superior brachygnathia.[2] The anomaly has occurred in some beef herds for several consecutive years and has affected 2–46% of the calf crop.[9] In a case reported from Ireland, the affected beef herd consisted of Hereford, Simmental, and Friesien cows bred to a Hereford or Charolais bull. The pregnant cattle were self-fed grass silage preserved with Kofasalt (calcium formate, sodium nitrite, and hexamethylene tetramine). Affected calves, were characterized clinically by disproportionate dwarfism, varying degrees of micromelia, limb rotation, joint laxity, and skull abnormalities.[5] Inferior and superior brachygnathia were present. Radiographically, the diaphyses were grossly foreshortened and thickened, the epiphyses were enlarged, misshapen and flared with increased opacity on some radiographs.[5] Histologically, there was chondrodystrophic of the metaphysis of the dwarf long bones. Consistent changes in organ weights or in trace element status were not present, and there was no evidence of infectious agents. There was no evidence of an inherited basis for the abnormal calves.

The epiphyses of the long bones are abnormal with overgrowth of chondrocytes and delayed mineralization. The common defect is one of growth plate maturation. The secondary ossification centers are slow to develop. Perinatal mortality is higher in affected calves than for normal calves in the same herd. The joint laxity may cause problems with dystocia. Within a few weeks after birth, the joints in surviving calves become stable, and calves walk normally.

SLIPPED CAPITAL FEMORAL EPIPHYSIS IN CALVES

This occurs in newborn calves of the well-muscled, rapidly growing European breeds, such as the Charolais, Maine-Anjou, and Simmental. It is characterized by varying degrees of lameness, palpable crepitus over the greater trochanter on passive manipulation of the affected limb, muscle atrophy in longstanding cases, and prolonged recumbency. Some calves carry the affected limb or drag the foot, whereas others tolerate slight weight-bearing during standing or walking. Most calves are lame at birth or within a few days after birth. About 75% of cases are associated with a dystocia and forced traction delivery.[1]

Laboratory stress testing of calf femurs found that mechanically induced fractures had configurations and locations similar to those found in clinical cases associated with forced extraction.[2] The breaking strength of all femurs was within the magnitude of forces calculated to be generated when mechanical devices are used to assist delivery during dystocia. It is suggested that the femur is compressed during force extraction when the pelvis of the calf is wedged in the pelvis of the dam in anterior presentation. Every effort must be employed to avoid premature engagement of the calf's stifle into the pelvic cavity to avoid or correct a 'stifle lock'.

Radiographically, there are varying degrees of displacement of the femoral neck from the head. In chronic cases there is partial resorption of the femoral head. Excision arthroplasty has been attempted with some encouraging results.

The disease must be differentiated from perinatal **femoral nerve degeneration** and neurogenic atrophy of the quadriceps femoris muscle which also occurs most commonly in the same breeds of cattle. The right hindleg is most commonly affected and affected calves are unable to bear weight on the leg; there is obvious neurogenic atrophy of the quadriceps muscle.[3] The problem has been treated by stall rest, femoral head and neck excision, and open reduction by use of Knowles pins, multiple intramedullary pins, or interfragmentary compression screws.[4]

Slipped capital femoral epiphysis has also been reported in cattle 3–5 months and 1.5–2.3 years of age.[3] Trauma is the suspected cause. If early diagnosis can be made, intramedullary pinning can provide a good long-term prognosis in cattle when function as a breeding animal is important to their future value.

TAIL-TIP NECROSIS IN BEEF CATTLE

Tail-tip necrosis occurs in cattle housed in confinement on slatted floors. The disease has occurred in steers, heifers, and bulls being fed for beef production.[1,2]

The lesion is caused by a traumatic injury of the tail caused by tramping of the tail. The lesion begins at the tip of tail followed by varying degrees of extension proximally. Initially, the tip of the tail is swollen, followed by inflammation and suppuration. Histopathological changes are compatible with cutaneous ischemia as a pathogenetic mechanism.[3] Extension of the infection can result in metastases to other parts of the body, resulting in abscesses and osteomyelitis. Affected cattle do not grow normally and deaths from pyemia may occur. The morbidity is about 5%. Approximately 10% of affected animals may be condemned for osteomyelitis and abscessation.

Risk factors

These include slatted concrete floors, close confinement, warm seasons, and a body weight above 200 kg. The risk increases as the space allotment, expressed as kg animal per m^2 pen increases from approximately 165 kg/m^2. Tail tramping is more frequent in slatted-floor pens with lower space allotment (1.5 m^2 per head) than in similar pens

with higher space allotment (2.4 m^2 per pen head). In an Ontario study, no case of tail-tip necrosis was diagnosed in solid-floor barns, while 1.36% of cattle in slatted-floor barns were either treated or slaughtered for tail-tip necrosis.[2] In a mail survey of feedlots in Ontario, 96% of 71 feedlots with slatted floors, but only 5% of 184 feedlots with solid floors, reported a problem with tail-tip necrosis from 1982 to 1986.[3] Of 441 tails inspected at slaughter plants, 34.5% were affected, with 3.4% involving skin lacerations and infection, and 4.3% amputated before slaughter.[3] Most cases occur from May to September when the temperature is above 18°C. This may be associated with increased contamination due to increased humidity and temperature under confinement conditions.

In slatted-floor barns, abnormal locomotor patterns occur from 20 to 25% of the times animals get up and lie down.[2] When animals get up abnormally, they first rise in their front, and consequently assume a dog-like sitting posture. In order to obtain momentum to rise in the rear, they then start to sway back and forth. The tail may become pinched between the hock of the rocking animal and the floor, resulting in blunt trauma to the tip of the tail.

TREATMENT

Treatment consists of early amputation combined with intensive antimicrobial therapy. Early detection is important. During warm months, cattle confined on slatted floors and weighing more than 200 kg should be closely inspected at least 2 or 3 times weekly. This includes palpation of all tail tips because early lesions are difficult to see.

CONTROL

This is dependent on providing sufficient space for housed cattle on slatted floors.

TOE ULCER AND NECROSIS OF THE APEX OF THE PEDAL BONE OF CATTLE

ETIOLOGY

A toe ulcer is a defect in the white line at the apex of the sole in adult cattle.[1] Lameness does not occur in the early stages but discomfort gradually develops at which stage the animal carries the foot further forward than normal. The etiology is not well understood. In one series of cases, overtrimming using a grinding disc and/or perforation of the sole was considered a major cause (49%), laminitis in 30%, and traumatic injuries in 11%.[2]

EPIDEMIOLOGY

In South America, where dairy herds are pastured and supplemented with concentrate and corn silage, toe ulcers are common lesions in heifers from 15 to 60 days after calving.[3] Two types of toe lesions are usually presented. One is a single claw horn defect occurring in Zone 1 which after further examination, granulation tissue is often observed. This lesion responds well to local treatment and the application of an orthopedic block on the healthy claw. The second type of lesion is more severe and includes necrosis of the pedal bone, complicated by secondary infection.

CLINICAL SIGNS

Clinical signs of apical pedal bone necrosis vary widely depending on the severity of the lesions, the number of claws involved and the causative factors. A marked-to-severe lameness may occur in cows with one claw affected, and a severely stilted gait in cows with two or three affected claws. In some cases, the lameness is so severe that the initial impression from a distance was that of a neurological disease because of the severely stilted, convulsive limb movements at rest and walking. The involvement of the pedal bone can be determined by clinical examination, inserting a probe or by direct visualization of the discolored and exposed apex of the distal phalanx.

PATHOGENESIS

The gross pathological findings of affected claws vary from moderate topical inflammatory signs of the corium at the toe of the claw, to severe and extensive necrosis and osteomyelitis of the pedal bone.[1] Histologically, there are different types of demarcation of the necrotic bone. Mixed infections are common.

Radiographically, the degree of involvement of the distal phalanx can be clearly identified, facilitating the choice of surgical therapy.[1]

TREATMENT

Treatment options include excision of necrotid bone using a bone curette, resection of the necrotic apex of the distal phalanx, and digital amputation in severe cases.[2]

DIFFERENTIAL DIAGNOSIS

Toe ulcers must be differentiated from toe abscesses which occur in yearling cattle and beef calves grazing irrigated pastures in the fall at which time they may be lame due to a toe abscess.

Diseases characterized by involvement of the skin

PITYRIASIS ROSEA

Pityriasis rosea is a condition of man. The condition in pigs is not the same because of a prominent component of eosinophils and confluent zones of epidermal necrolysis. Dermatopathological authorities have suggested that the condition be renamed pustular psoriasiform dermatitis of pigs.[1]

This skin disease of pigs resembles ringworm closely but skin scrapings do not reveal the presence of fungal hyphae or spores, and cultures for fungal growth are usually negative. Treatment with standard preparations used for ringworm is usually ineffective, although spontaneous recovery may occur.

The disease occurs in sucking pigs[2] and young pigs in the 10–14 weeks age group. Up to 50% of each litter and herd may be affected and in large groups of feeder pigs there may be only individual pigs or the majority of the group with lesions. The disease is usually innocuous, although digestive disturbances, particularly anorexia and, to a lesser extent, diarrhea and vomiting may accompany the appearance of lesions and affected pigs lose some body weight. There is no fever. Usually the condition resolves spontaneously after 2–4 months.

Lesions occur most commonly on the ventral abdomen but may spread to the rest of the body. They commence as small, red nodules which enlarge to flat plaques and become covered with thin, dry, brown scales. The lesions appear to enlarge centrifugally, leaving a center of normal appearance surrounded by a narrow zone of elevated, erythematous skin covered by typical scales. Individual lesions are generally circular except that they often coalesce to produce a large, irregular lesion. There is little irritation and the skin lesions, although obvious, are superficial. There is no loss of bristles. Histologically, the lesions show a progression from acute to chronic with a dense superficial and deep perivascular infiltrate of eosinophils, lymphocytes, and histiocytes.[1]

The cause is unknown, although infectious, genetic and allergic causes have been suggested and there is strong evidence of familial susceptibility, either through inheritance or by vertical transmission of an infectious agent.[3,4] Transmission experiments have been unsuccessful and the disease has been observed in SPF pigs

produced by cesarean section.[5] By analogy with a similar condition affecting man, it may be a viral infection. Treatment appears to be completely ineffective but in general consists of the local application of a salve containing 5% salicylic or iodized mineral oil. Affected pigs should be isolated from the group. Spontaneous recovery occurs in 6–8 weeks in most instances.

ANHIDROSIS (NON-SWEATING SYNDROME, PUFF DISEASE, DRY COAT)

Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

ETIOLOGY

The etiology of anhidrosis is unknown, but involves a reduction in the sensitivity of the sweat gland to β-2 adrenergic stimulation, the normal stimulus for sweating in the horse.[1] Hypothyroidism does not contribute to anhidrosis.[2]

EPIDEMIOLOGY

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates including tropical and semi-tropical regions.[1]

The overall prevalence is approximately 6% in Florida, with the highest prevalence (25%) in horses in training and the lowest prevalence (1%) in young horses.[2] There is no reported sex or color predilection. Both native and imported horses are affected, apparently with similar prevalence.[3] Among native horses the age of onset of the condition ranges from 1 year to 10 years.[3] Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year.[3] The incidence and severity of the disease are highest in the hotter season.

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is inability of affected horses to exercise and compete in athletic events.

PATHOGENESIS

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are well innervated, and sweating is controlled by a combination of hormonal (β-2 adrenergic) and neural factors.[4] Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline.[4] Anhidrotic horses have lower initial and peak rates of sweat production, and lower overall sweat production, than do normal horses during intravenous infusion of epinephrine.[5] Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses includes diminished glandular sensitivity to epinephrine, failure of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Sweating is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

CLINICAL FINDINGS

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating may be limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and may not lather during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face.

Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease 'dry puffer'. The animal's appetite declines and it loses weight. Athletic performance is severely compromised. High body temperatures are observed after exercise, sometimes reaching 41.5–42°C (107–108°F) and persist for long periods.

The **prognosis** is poor for athletic function for affected animals that remain in hot and humid environments, but the condition may resolve if the horse is moved to a cool climate.

CLINICAL PATHOLOGY

Plasma epinephrine concentrations are reported to be higher in affected horses than in unaffected horses,[6] but this has not been a consistent finding among studies.[5]

Diagnostic confirmation is achieved by demonstrating reduced sweating in response to **intradermal injection of epinephrine**, or the β-2 adrenergic agonists, terbutaline and salbutamol.[7] A crude test involves the intradermal injection of 0.1 mL of a 1:1000 dilution of epinephrine. If the horse sweats then it is not considered to be completely anhidrotic. A **semiquantitative test** using epinephrine, terbutaline, or salbutamol may be useful in identifying partially anhidrotic horses.[7] Normal horses sweat when 0.1 mL of 1:1000 000 epinephrine is injected, while partially anhidrotic horses sweat only with higher concentrations (1:10 000 or 1:1000). Injections are usually made using small gauge needles (25 g) into the skin over the lateral aspects of the neck.

NECROPSY FINDINGS

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology including flattening of cells and loss of luminal microvilli and a reduction in the number of secretory vesicles. These findings are thought to be a consequence, rather than a cause, of the disease.

TREATMENT AND CONTROL

There is **no specific treatment** that restores the horse's ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered **electrolyte supplements**, but without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be insured.

Administration of **thyroid hormone supplements** is not warranted, and may be dangerous by increasing the metabolic rate, and therefore heat production, of affected horses. **Vitamin E** administration has no demonstrated efficacy.

Removal of affected animals to cooler climates is often necessary, although air conditioning of stables and maintenance of horses in higher country where they can be returned after a day's racing may enable susceptible horses to be kept locally.

BOVINE OCULAR SQUAMOUS-CELL CARCINOMA

Ocular squamous-cell carcinoma, often referred to as 'cancer eye', is one of the most common neoplasms of cattle.

Synopsis

Etiology Genetic-environmental interaction. Lack of pigmentation around the eye and solar radiation.
Epidemiology One of most common neoplasms of cattle; mostly in beef cattle breeds (Herefords, Simmental) lacking pigment around the eye; animals over 5 years of age.
Solar radiation major risk factor.
Signs Precursor lesions, single or multiple plaques on eyelid or conjunctiva except the cornea or pigmented lid may regress, or lead to carcinomas of sclera resembling papillomas with crumbly, necrotic ulcerated mass attached to the eyelid causing irritation to eye and conjunctiva and excessive lacrimation and pus. Invasion of surrounding tissues of eye and possibly to nearby lymph nodes.
Clinical pathology Histology of lesion.
Lesions Squamous cell carcinoma.
Diagnostic confirmation Biopsy and histology.
Differential diagnosis list

- Pinkeye
- Lymphoma of periorbital tissues.

Treatment Excision by cryosurgery. Radical surgery may be necessary. Immunotherapy with vaccines has been attempted.
Control Breeding program to increase degree of pigmentation in Hereford cattle.

ETIOLOGY

A genetic-environmental interaction has been proposed as the cause. A relative **lack of circumocular and corneoscleral pigmentation**, both of which are heritable, increases the probability of lesion development when the animal is exposed to a carcinogenic agent like the **ultraviolet component of sunlight**. The carcinoma has been regarded as a papilloma-associated tumor because papilloma virus can be found in the precursor lesions, and papillomavirus DNA in the carcinomas. However, advanced virological techniques have failed to reveal any association between the virus and the tumor.[1]

The p53 gene product is highly expressed in bovine BOSCC, which provides support for its role in BOSCC tumorigenesis.[2]

EPIDEMIOLOGY

Occurrence

Bovine ocular squamous cell carcinoma is a common neoplasm of the eyelids and the eyeball of cattle and one of the most common neoplasms of cattle. The disease is most common in beef cattle which are exposed to more sunlight than dairy cattle. The tumors are uncommon in cattle younger than 5 years and are hardly ever seen in cattle younger than 3 years. The condemnation rate of cattle with ocular squamous cell carcinoma in Canada is about 30% of cases.[3] A squamous cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.[4]

Risk factors

The heritabilities, phenotypic, and genetic correlations of lid and corneoscleral pigment and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 states of the US and one Canadian province. The results indicated that lid and corneoscleral pigment were heritable and genetically correlated.[5] These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to some carcinogenic agent such as ultraviolet light.

In Zimbabwe, ocular squamous cell carcinoma was frequently observed in five breeding herds of Simmental cattle.[6] In these herds, initial signs of the disease were evident in cattle about 3 years of age and gradually the prevalence increased to over 50% in animals over 7 years of age.[6] It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same environment which suggests a genetic predisposition for the tumors in Simmental cattle. In Zimbabwe, the tumor is not recorded in fully-pigmented cattle breeds.

The association between ocular squamous cell tumors and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation.[7] Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to high levels of radiation develop the disease at younger ages.[7]

Economic importance

The disease results in serious economic consequences through lessened productivity and carcass condemnations. Commercial cattle can be culled early without much loss, because only the head is condemned. Purebred cattle are more of a problem because of the difficulty of deciding when euthanasia must be the humane decision, rather than another attempted extirpation of the eye.

PATHOGENESIS

The initial lesion may be on the eyelid or any structure in the conjunctival sac, except the avascular cornea or pigmented eyelid. Lesions can encroach on these tissues from others nearby, carrying a blood supply with them.

The lesions develop through three stages. The first two, a plaque and then a papilloma, are non-malignant and have high regression rates. The third stage is the squamous cell carcinoma which does not regress. The tumor is located in the sclera adjacent to the lateral limbus, in the membrana nictitans (third eyelid), or in the lower eyelid. It is an invasive tumor, metastasizing along the draining lymphatics into cervical lymph nodes. Primary lesions of the lids are most likely to metastasize to these nodes.

Animals do not appear to develop resistance to the cancer; only a few cows with the disease develop measurable antibodies in their sera. It is one of the characteristics of this disease that the carcinomas appear to produce immunosuppressive substances, and removal of tumor mass reduces blood levels of them.

In countries and in herds where ocular carcinoma is common, it is not unusual to encounter lesions on the labia of the vulva especially if there are patches of unpigmented skin.[8]

CLINICAL FINDINGS

Typical precursor lesions are single or multiple plaques of gray-white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva. **Plaques** may develop into papillomas and acanthomas of the skin of the eyelids, also included as precursor lesions. Squamous-cell carcinomas may develop from any of these precursors which may also regress spontaneously. The proportion that regresses is of the order of 80%.

Classic BOSCC lesions resemble papillomas with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common but metastases to nearby lymph nodes and to viscera occur in only a few cases and then only late in the course of the disease.

CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically and cytological examination or biopsy is recommended for definitive diagnoses. The cytology of squamous cell carcinomas in domestic animals has been described.[9]

DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% is recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:

- Pink eye and its complications which results in excessive lacrimation and purulent material, and
- Lymphoma of the periorbital tissues which usually manifests as exophalthmos.

TREATMENT

Excision, sometimes by cryosurgery, is widely practiced in cattle. Results are good and treatment by the use of radioactive implants has also aroused favorable comment. Recurrence, or the development of new lesions at the same site, is a common sequel. Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in some bovine cases. It is often combined with immunotherapy, e.g. with BCG vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. That there is a significant immune body response at the normal tissue-corneal interface has been demonstrated, but whether this plays any part in the rejection of the tumors is not known. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.[10]

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors with a higher recovery rate after the use of 200 mg of lyophilized tumor extract as compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease. Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.[11]

Other treatments which have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include electrothermal hyperthermia and combinations of the above procedures.

CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford cattle, it is suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed.[5] A positive approach to the problem would be to crossbreed susceptible *Bos taurus* cattle with *Bos indicus* cattle which always have pigmented eyelids and have much less eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinomata of the vulva, but the neoplasm does not occur on both sites in the one cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

EQUINE OCULAR SQUAMOUS-CELL CARCINOMA

Squamous cell carcinoma is one of the most common neoplasms of the horse and is the most common tumor of the eye and orbit but the rate of occurrence is low. The reported frequency has been highest in animals lacking periocular pigmentation and is more common in Appaloosa, albino, and color dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in draft horse breeds, Appaloosas, Paint Horses, Thoroughbreds, and Quarter Horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings.[1] The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8–10 years.[2] In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, squamous cell carcinoma was the most predominant tumor type and Haflinger horses accounted for 69% whereas their occurrence in the hospital population was 5%.[3]

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases[4] which may be a reflection of the high level of solar radiation in southeastern US. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%; whereas with only surgical excision the cure rate was 55%.[4] Best results with treatment are seen when surgical intervention is early.[5] In horses, treatment is largely surgical but all of the immunological techniques developed for cattle have been used including local irradiation therapy with ^{90}Sr or ^{222}Rn.[2]

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva but the eyelids and cornea are also involved. A case of limbal squamous cell carcinoma with invasion into the cornea and uvea of 12-year-old Haflinger gelding has been described.[6] On initial presentation, a light-pink raised mass on the temporal limbus and conjunctiva of one eye was observed. Squamous cell carcinoma was confirmed histologically after keratectomy and cryotherapy. Seven months later, a smooth pink, progressively enlarging mass was observed within the cornea. Ultrasonographically, the mass was found infiltrating the corneal stroma and the anterior chamber. The globe was surgically removed. Histologically, a diagnosis of corneal ocular squamous cell carcinoma with deep stromal invasion, infiltration of the uveoscleral meshwork and iridocorneal angle and resulting intraocular extension was made.

A pigmented squamous cell carcinoma of the conjunctiva of a 17-year-old horse has been described.[7]

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplastin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (^{90}Sr) cobalt 60 (^{60}Co), gold 198, iridium 192 (^{192}Ir), cesium 137, iodine 125 (^{125}I), and radon 222 (^{222}Rn).[1] In a series of 157 cases of ocular and adnexa squamous cell carcinoma, those treated with adjuvant radiation therapy had a significantly lower recurrence rate, compared with those treated without adjuvant radiation therapy, independent of anatomic location.[1]

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses.[3] Sophisticated equipment is not required and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa or orbit, which clinically mimics true neoplasms.[8] Cases are characterized by a uniocular, pink proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory characterized by predominantly lymphocytic infiltrates. The cause is unknown but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with anti-inflammatory therapy, or anti-inflammatory therapy alone.[8]

OCULAR SQUAMOUS CELL CARCINOMA IN GOATS

A well-differentiated ocular squamous cell carcinoma has been described in twin goats.[1] The twin goats, one male and one female, were 3 years of age. Both animals had pigmented eyelids and had been reared at an altitude of 760 m above sea level in Italy. The lesions were very advanced when first examined. There was a history of bilateral ocular disease and impaired vision of 24 months duration. In the affected eyes, a firm mass with a fleshy appearance was evident, covering the entire cornea and protruding through the palpebral fissure. A bilateral ocular mucopurulent discharge, associated with corneal plaques, neovascularization and edema, was also present in both animals.

Histologically, cords and islands of squamous epithelial cells proliferated deeply throughout the cornea and invaded the basal layer, limbus, iris, and cilary body, and other features, characteristic of a well-differentiated ocular squamous cell carcinoma.

Biomolecular studies to the identification of *Papillomavirus*-related DNA sequences within the neoplastic ocular parenchyma of both animals but immunohistochemical and ultrastructural examinations did not demonstrate viral particles.

'COCKLE'

This is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt.

Cockle is not usually diagnosed clinically but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection.[1] The lesions are the result of an immune response in some sheep to infestation with the biting louse *Bovicola ovis*. The occurrence of cockle and its severity is positively correlated with the severity of the louse infestation[2] and sheep that develop lesions have *B. ovis*-specific homocytotrophic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naive lambs.[3]

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, 'scatter cockle', are attributed to infestation with *B. ovis*, and this is the most common cause but 'rib cockle' may be a hypersensitivity to infestation with the sheep ked *Melophagus ovinus*. Pelt lesions in the dorsal midline region are usually due to infection with *Dermatophilus congolensis*.[1]

CONTROL

This rests with the control of *B. ovis*. For cockle control sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations.[4] Prelambing dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

WOOLSLIP, WOOL LOSS

Woolslip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the **rear half of the back**.[1] This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histological examination of skin biopsies show that in affected sheep the wool follicles are in the active anogen stage rather than the inactive telogen phase of unaffected cohort sheep and the wool regrows immediately following loss.[1] The loss of wool **starts 2–3 weeks after shearing**. All breeds are equally susceptible and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathological process which damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids and the current explanation for the wool shedding that occurs with the woolslip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in woolslip affected sheep are within the normal range and there is no epidermal change as occurs in zinc deficiency.

The **prevention** of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and insuring a good nutritional plane in the post-shearing period.[1] This hypothesis as to cause may not be correct as the syndrome has also been seen in the

summer in Wiltshire shorn sheep which had little history of stress in the period immediately preceding the woolslip.[2]

Woolslip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backline also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.[3]

Impairment of wool growth and a **thinning of fiber diameter** can occur during the course of any **severe disease** such as bluetongue, pregnancy toxemia, or foot rot temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength and the condition has the name **tender wool.** Following recovery from the inciting disease the wool growth is normal but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fibre diameter, often with a change in crimp character and discoloration due to entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as **wool break**. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth and occasionally result in fleece loss in sheep.[4,5] Wool loss associated with pruritus occurs in association with external parasite infestations (Ch. 27) and with scrapie and pseudorabies in ruminants.

Pelodora dermatitis, characterized by thickening of the skin and complete wool loss in affected skin areas is recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite, *Peladora (Rhabditis) strongyloides* is a free living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histological examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.[6]

WOOL EATING

Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called **shimao zheng,** occurring in a region of the Gansu province of China has wool eating as its primary manifestation. The disease has a seasonal occurrence with the peak incidence in January through April. Both goats and sheep are affected but the incidence and severity is much higher in goats where 90% may show signs. Affected animals bite the wool or hair off their own or other animals bodies particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair and aggregated foci of lymphocytes in the dermis. Controlled trials have shown the condition can be corrected by supplementation with sulphur, copper, and iron.[7,8] Wool eating is also recorded in Israel possibly associated with trace element copper and zinc deficiency.[9] Wool and hair loss in individual sheep and cattle in association with excessive licking is recorded and are postulated as psychogenic dermatoses.[10]

REFERENCE LABORATORY VALUES

Reference values for some frequently measured variables in blood and serum are provided as a guide. Values of these variables from healthy animals vary depending on many factors including age, breed, sex, diet, geographical habitat and methods of sample collection and laboratory measurement. The values listed below are compiled from a variety of sources including the clinical laboratories of the Western College of Veterinary Medicine at the University of Saskatchewan, the College of Veterinary Medicine at The Ohio State University, and Kaneko JJ. *Clinical biochemistry of domestic animals*, 5th edn. New York: Academic Press, 1997.

Tables of reference values for newborn foals and calves are provided elsewhere.

Appendix 3

DRUG DOSES AND INTERVALS FOR HORSES AND RUMINANTS

Suggested drug doses and intervals for horses and ruminants. Dosages listed are general recommendations and might not be optimal or efficacious in all instances and might need to be adjusted depending on the disease, its severity, patient factors including but not limited to age or diet, and because of regulatory considerations regarding milk and meat withholding times in animals intended as human food. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that could be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses, such as intramammary preparations, are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), intrarticular (IA), intramammary (IMM), intraperitoneal (IP), inhalation (IH), per rectum (PR), topically (TO), or subconjunctivally (IO). Drugs recommended not to be given to certain species are indicated by NR.

	Horses			**Ruminants (cattle, sheep, goats)**		
Drug	***Dose (mg/kg)***	***Interval (h)***	***Route***	***Dose (mg/kg)***	***Interval (h)***	***Route***
Acepromazine maleate	0.04–0.1	SD	IM, IV, SC	0.03–0.1	SD	IM, IV, SC
Acetazolamide	2.2	6–12	PO			
Acetic acid				10–20	SD	PO
Acetylcysteine	8 g, TD (for (retained meconium) 140	SD 24	PR PO			
Acetylsalicylic acid (aspirin)	10–20	48	PO	50–100	12	PO

Appendix 4

DRUG DOSES AND INTERVALS FOR PIGS

Suggested drug doses and intervals for pigs, and concentrations of medicaments in feed. Dosages listed are general recommendations and may not be optimal or efficacious in all instances and may need to be adjusted depending on the disease, its severity, patient factors such as age or diet, and because of regulatory considerations regarding milk and meat withholding times in food animals. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that may be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses are denoted byTD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), or intraperitoneal (IP). One ton = 1016 kg.

	Pigs		
Drug	***Dose (mg/kg) or (Concentration in feed or water)***	***Interval (h)***	***Route***
Acepromazine maleate	0.03–0.5	SD	IM, IV, SC
Acetazolamide	6–8	SD	IV, IM, PO
